Linguistic frameworks are used in a number of fields of study, such as grammar (including word classes, categories, morphology, and syntax), graphology, lexis, phonology, pragmatics, and semantics. More specifically, there are seven main language frameworks: *lexis*, the vocabulary of a language; *semantics*, the study of how meaning is created through words and phrases; *grammar*, which includes the system of rules that governs how words and sentences are constructed, the system that groups words into classes according to function, the system of rules about how words function in relation to each other (syntax) and individual units that make up whole words (morphology); *phonology*, the study of sounds in a given language; *pragmatics*, or language in use, meaning how social aspects and intentions affect people's language choices; *graphology*, the study of the appearance of the writing; and *discourse*, the whole piece of text in which more than one sentence is analyzed together with its contexts, info-graphic, audiovisual, and extralinguistic features).

Applications and Usage

Linguistic frameworks have further applications. They are used in the philosophy of language, metaphysics, and philosophy of science. They characterize a chosen language or a set of analytical principles that provide the method and criterion for the formulation of any significant assertion and its solution within the framework. A body of significant knowledge can only be justified by reference to the principles or rules that make up the framework. More precisely, linguistic frameworks enable the operation and logical systematized categorization of the phenomena and concepts within the fields of study and help those fields make references to the real world. The framework could be construed as the basis

for reaching an agreement about any disputed problem.

Different frameworks reflect different ways of talking about the world. But once we have adopted a framework, we must obey all its rules and principles. It could be assumed that any answer to a question about the kinds of entities conceptualized by a language is relative to a framework.

Linguistic Frameworks Used in Linguistic Annotation

Linguistic frameworks are most widely used in linguistic annotations. *Linguistic annotation* signifies any descriptive or analytic notations applied to raw language data. The basic data may be in the form of time functions—audio, video, and/or physiological recordings—or it may be textual. The added notations may include transcriptions of all sorts (from phonetic features to discourse structures), part-of-speech and sense tagging, syntactic analysis, *named entity* identification, coreference annotation, and so on. Although there are several ongoing efforts to provide formats and tools for such annotations and to publish annotated linguistic databases, the scarcity of widely accepted standards has emerged as a critical problem since the late 20th century. Some proposed standards have focused on file formats, while other scholars have argued that standards should instead be focused on the logical structure of linguistic annotations and that researchers thus need to analyze a wide variety of existing annotation formats and demonstrate a common conceptual core: the annotation graph. This would provide a formal framework for constructing, maintaining, and searching linguistic annotations while remaining consistent with many alternative data structures and file formats.

Information Granularity in Applying Linguistic Frameworks

The framework must provide means to represent all varieties of linguistic information (and possibly also other types of information). This includes representing the full range of information from the very general to the information at the finest level of granularity.

In addition, the framework must handle all potential media types, including text, audio, video, and image, and should provide common mechanisms for handling them. The frameworks rely on existing or developing standards for representing multimedia.

Descriptors, information categories, principles, and standards should be fixed in a formal semantic way. The frameworks should also provide common procedures for input interpretation and output generation.

Fields That Apply Linguistic Frameworks

Because linguistic frameworks cover a wide range of systems that pertain to different spheres, a number of related disciplines make extensive use of their resources. The following fields are most commonly noted in this respect.

Computational linguistics is the study of language using the techniques and concepts of computer science, especially with reference to the problems posed by the fields of machine translation, information retrieval, and artificial intelligence. Computational linguistics uses extensively syntactic rules, syntactic trees, and procedures for programming purposes; hence, the usage of linguistic framework is an indispensable part.

Neurolinguistics is the study of the neurological basis of language development and use in human beings, especially of the brain's control over the processes of speech and understanding. Consequently, neurolinguistics constantly refers to semantic, syntactic, lexical, and pragmatic frameworks.

Psycholinguistics is the study of the relationship between linguistic behavior and the psychological processes to underlie it. The processes may involve memory, attention, thought, and others. Hence, grammar, semantic, pragmatic, and discourse frameworks often lend to psycholinguistic studies.

Sociolinguistics studies the interactions between language structure and functioning of society. Pragmatic, discourse, lexical, and phonological frameworks are often used in sociolinguistic investigations.

Statistical linguistics studies the quantitative properties of language. Usage frequencies of acceptable or unacceptable linguistic structures, as well as compiling corpora, are major objects of investigation. Therefore, the entire stock of linguistic frameworks is made use of at one point or another.

Mathematical linguistics studies mathematical properties of language, using concepts from such fields as algebra, computer science, and statistics; hence, it makes wide use of syntactic, phonological, and other linguistic frameworks.

Anthropological linguistics is the study of language variation and use in relation to the cultural patterns and beliefs of humankind, as investigated using the theories and methods of anthropology and referring to lexical, phonological, and discourse frameworks.

Applied linguistics is the application of linguistic theories, methods, and findings to the elucidation of language problems that have arisen in other domains. The term is especially used with reference to the field of foreign language learning and teaching, but it applies equally to several other fields, such as stylistics, lexicography, translation, and language planning, as well as to the clinical and educational fields. Since it covers a wide array of issues, it makes use of the entire linguistic framework.

Biological linguistics is the study of the biological conditions for language development and use in human beings, with reference both to the history of human language and to child development. Syntactic, phonological, morphological, and lexical frameworks often lend to biolinguistic studies.

Clinical linguistics is the application of linguistic theories and methods to the analysis of disorders of spoken, written, or sign language. Any linguistic framework may contribute to clinical studies depending on the topic of research.

Educational linguistics is the application of linguistic theories and methods to the study of the teaching and learning of a language, especially of a first language, in schools and other educational settings. Due to its wide range of issues under investigation, the field of educational linguistics refers to any linguistic framework depending on the circumstances of any particular study.

Ethnolinguistics is the study of language in relation to ethnic types and behavior, especially with reference to the way social interaction proceeds. Discourse, lexical, and pragmatic frameworks are of particular interest, but not exclusive to the field.

Geographical linguistics is the study of the regional distribution of languages and dialects, seen in relation to geographical factors in the environment. Phonological and lexical frameworks are particularly important to such studies.

Philosophical linguistics is the study of the role of language in the elucidation of philosophical concepts, and of the philosophical status of linguistic theories, methods, and observations. Pragmatic and discourse frameworks fall within the realm of these studies.

The overall field of *linguistics* itself provides an invaluable conceptual framework to a number of disciplines that cross-feed from its studies, findings, sources, concepts, and rules.

LINGUISTICS, CONTEMPORARY

Contemporary linguistics stands at the crossroads of multiple disciplines. It juxtaposes the interests and research questions of diverse fields that might seem unrelated at a glance. However, human language is what provides common research ground for these disciplines. Therefore, contemporary linguistics is the discipline that studies human language. Language of course figures centrally in our lives. Humans discover their identity as individuals and social beings when they acquire language in childhood. Language serves as a means of cognition and communication. It helps us produce thoughts and cooperate with other people. It provides for present needs and future plans. Language seems to be an essential feature of humanity, which enables individuals to rise above the condition of other living being and distinguishes humans from other species. That is why language is the study object of various disciplines.

Language Features

One of the primary and significant features of a language is *arbitrariness*: The forms of linguistic signs bear no natural resemblance to their meaning. The link between them is a matter of convention,

and conventions differ radically across languages. However, there is an exception. Onomatopoeic words resemble to a degree to the sounds that they designate (e.g., Woof! Grrr!).

Another important feature of language is *duality*. Human language operates on two levels of structure. At one level are elements that have no meaning in themselves but which combine to form units at another level that do have meaning. For instance, letters combine in different ways to form words that have meanings. The duality feature operates both on spoken and written levels and indicates the flexible nature of a language.

A further interesting feature of a language is that it enables us to categorize reality and express the categories through language. This important function and feature that language has is *ideational* function. Through ideation function, humans are able to classify and categorize the reality, the environment around them.

Displacement is the next feature of language. It enables speakers to refer to the objects and events that are distant in space or occurred in another time.

Language is meaningful and understandable to other speakers, hence, its *semanticity* feature.

Through a limited number of symbols, language produces innumerable sentences, hence, its *generativity* or *productivity* feature.

Language has rules that govern how symbols can be arranged. These rules allow people to understand messages in that language even if they have never encountered those messages before. Language is not a continuous flow of sounds but a systematically and discretely arranged unity of separate sounds/phonemes. Thus, language has the feature of *discreteness*.

Linguistic Relativism Versus Language Universal

Perhaps the most widely known debate pertaining to *contemporary linguistics* is that between relativist and universalist standpoints. While relativists claim that each language is the reflection of the unique culture and mentality of the speakers of the given language (hence, linguistic relativity), the universalist standpoint (the well-known theory attributed to Noam Chomsky) argues that there is an innate linguistic capacity in all humans to acquire and use the basic rules and structures (parameters)

of any language (hence, the concept of *universal grammar*). Linguistic relativism is also known as the *Whorf hypothesis* or *Sapir-Whorf hypothesis* (named after the linguists Benjamin Lee Whorf and Edward Sapir), which is the view that language shapes cognition; that is, concepts and ways of thinking depend on language. People who speak significantly different languages, then, view the world differently. Moreover, there exists the concept of *linguistic determinism*, which reflects the strong version of relativism and implies the idea that language and its structures limit and determine human knowledge or thought, as well as thought processes such as categorization, memory, and perception. The term implies that people of different languages have different thought processes.

While relativists blame the universal standpoint for restricting the immense capacities of any language to mere structures and rules, universalists defend their stance by further explaining that it is exactly through an innate capacity to acquire the basic rules of any language that humans are able to produce innumerable lexical and grammatical units and to make them comprehensible to speakers of other languages. In fact, in modern linguistic thought, there are many intersecting points between the relativist and universalist positions since the arguments on both sides actually complement, rather than contradict, each other.

Functions of Language

It is noteworthy that from a universalist standpoint, language is *cognitive*. It is seen as a psychological phenomenon that reveals the human mind through the linguistic forms that it produces. However, the cognitive aspect is not the only feature of a language. In order to serve a societal function, it acquires *social* features as well. Hence, it possesses an important communicative function that enables humans to transfer and receive units of information among each other.

Dual Nature of Language and Linguistic Oppositions

As already mentioned, language is an intrinsically dual system. One such duality was identified and put forward by Ferdinand de Saussure, a Swiss linguist, in the beginning of the 20th century. By

duality, he meant the *langue* and *parole* components of a language, by which *langue* signifies the coded system of language rules and principles common to every speaker of that language, and *parole* is the idiosyncratic speech pattern of every individual of that language community.

The dual nature of language is noted by Noam Chomsky as well, who distinguishes between *competence* and *performance*. Closely similar to Saussurean *langue* and *parole*, Chomsky calls the rules and procedures that are commonly acquired by all speakers as *competence*, and the individual speech behavior of any individual as *performance*.

Another significant duality that Saussure put forward was that of the ideas of *synchrony* and *diachrony* in linguistic studies. Synchronic analysis studies the features of a language at the present moment, while diachronic study traces the development and evolution of language throughout centuries by identifying the linguistic changes that the levels of language system undergo. The changes and transformations are traced on all levels of language: phonological, phonetic, morphological, syntactic, lexical, semantic, and even pragmatic (which includes discursive and extralinguistic features).

Dual nature applies to principles of linguistic analysis as well. When conducting linguistic analysis on any level, linguists widely implement the *syntagmatic* and *paradigmatic* dimensions of analysis, *syntagmatic* revealing the horizontal, or linear, relations between the linguistic elements, and *paradigmatic* arranging the elements in a vertical pattern.

The opposition of *markedness* and *unmarkedness* is yet another linguistic feature that characterizes any language. The simplest and most explicit example to illustrate this duality is the existence of negative affixes, lexical units, or syntactic constructions alongside the positive ones (e.g., masked-unmasked, yes-no, went-did not go). While positive linguistic items are considered to be *unmarked*, negative units and constructions are usually considered *marked* during linguistic analysis.

Levels of Linguistic Analysis

Linguistic analysis of language is usually conducted on several levels, which are often closely interconnected and influence each other. Following are the levels that linguistic principles of analysis are

applied to *phonetics* (speech variations), *phonology* (sound variations, phonemes, and allophones), *morphology* (inflections and affixation that bear grammatical value in every language, allomorphs), *syntax* (sentence and phrase structures and means of constructing cohesive and coherent connections within and between sentences), *semantics* (analyzing variations in meanings of lexical or phraseological units), and *pragmatics* (the intentional use of certain linguistic means by speakers to achieve the desired communicative goals). The higher level of analysis goes as far as discourse, which entails longer textual, visual, auditory, graphical, and other extralinguistic elements that influence the overall coding and decoding of the entire speech act.

The study of allophonic manifestations—that is, how the sounds of speech are actually made—is the topic of research of phonetics. The study of phonemes and their relations in sound systems is the research topic of phonology. But these studies need to be seen as interrelated since their findings complement each other. Furthermore, the sounds organize in larger segments called *syllables*, which in their turn are stressed or unstressed. The fact causes the modification of sounds. Besides, sentences are pronounced with rising or falling intonation. All these issues fall under the study of phonetics and phonology.

The next stage of analysis is that of morphology, which studies inflections and word affixations that form grammatical categories and variations of tense, person, case, number, and so on. These derivative forms are called *allomorphs*. Therefore, word derivation, affixation, and inflection are studied on the level of morphology.

Moving on to the next stage of analysis, the syntactic level, the organization and connections of words into larger units are researched. The words organize themselves in phrases, sense groups, and sentences. The sentences organize into even larger units, paragraphs, textual chunks, or larger segments. The main organizing principle is the establishment of cohesive and coherent connections between the words and sense groups through various linking devices, such as conjunctions, adverbs, and so forth. In addition, sentences are studied through the analysis of their immediate constituents, and through the structures of syntactic trees that present building blocks of syntax and computational linguistics.

Morphological and syntactic analyses fall under the grammatical level of analysis, which is primarily concerned with identifying, categorizing, and understanding the structural features of a language. However, these levels of analysis are intrinsically intertwined with other levels of analysis, including the phonetic, phonological, semantic, and discursive levels.

In addition to structural levels of analysis, linguists conduct analysis at the semantic level, which is primarily concerned with the meanings of linguistic units. Componential analysis is implemented for the purpose of understanding the meaning of a linguistic unit. The elements of meaning are analyzed through semantic components, lexemes that carry denotational (and sometimes connotational) sense. Further sense relations between words and phrases are established through synonymy, antonymy, metonymy, polysemy, and so forth.

It is well established that all the aforementioned structural or semantic levels of analysis are indispensably connected with the context and extralinguistic parameters in which these structural or semantic elements are implemented. Hence, pragmatic analysis, discourse analysis, and intertextual analysis are often conducted in conjunction with each other.

The most widely used form of pragmatic analysis is the speech act method, which analyzes linguistic features in the process of speech or communication in which individuals are involved. According to pragmatic analysis, any statement or utterance produced during a speech act engenders three effects: locution, illocution, and perlocution. *Locution* is the expression of the statement itself, *illocution* is the intention that the speaker wants to achieve through making this statement, and *perlocution* is the effect that is made on another person toward whom the illocutionary force was directed. Perlocution could reveal how much the listener got persuaded, impressed, encouraged, or frightened by the speaker: What was the effect of the speech act? How successfully was it conducted? (Hence, the concept of felicity, or success, condition that is often referred to in this respect).

Further, it is often noted by linguists (especially pragmatists) that context is a *schematic* construct. It means that when people make an indexical connection, they do so by linking features of the

language with familiar features of their world, with what is established in their minds as a normal pattern of reality, or *schema*. It is not *out there*, so to speak, but in the mind. Hence, the achievement of pragmatic meaning is a matter of matching up the linguistic elements of the code with the schematic elements of the context. In addition to context, paralinguistic features are often considered during the analysis. Paralinguistic features include tone of voice, gestures, facial expressions, eye contacts of communicants that affect the communicative act and help decipher the implicit meanings and intentions of the utterances or statements that they make. Through the usage of relevant linguistic, pragmatic, paralinguistic, and extralinguistic means, the communicants establish the so-called *cooperative principle* that is the necessary precondition for mutual understanding and the realization of goals in the speech acts that they produce.

In summation, linguistic analysis is a complex and constantly developing process that involves multiple levels, procedures, and principles of scientific study.

Hybrid Disciplines

The following are the hybrid disciplines that have emerged as a result of merging linguistics with other disciplines in order to investigate issues of common interest. These disciplines make extensive use of linguistic frameworks: linguistic rules, concepts, and procedures.

Computational linguistics is the study of language using the techniques and concepts of computer science, especially with reference to the problems posed by the fields of machine translation, information retrieval, and artificial intelligence. Computational linguistics uses extensively syntactic rules and procedures for programming purposes; hence, the use of a linguistic framework is its indispensable part. In addition to this, computer programs are widely used to collect, systematize, and analyze vast corpora occurring in languages; that is, to produce and continuously extend corpus linguistics. Without these procedures, no level of modern linguistic analysis can be considered complete or final.

Neurolinguistics is the study of the neurological basis of language development and use in human

beings, especially of the brain's control over the processes of speech and understanding. Consequently, neurolinguistics constantly refers to semantic, syntactic, lexical, and pragmatic frameworks.

Psycholinguistics is the study of the relationship between linguistic behavior and the psychological processes that underlie it. The processes may involve memory attention, thought, and others. Hence, grammar, semantic, pragmatic, and discourse frameworks often lend to psycholinguistic studies.

Sociolinguistics studies the interactions between language and the structure and functioning of society. Pragmatic, discourse, lexical, and phonological frameworks are often used in sociolinguistic investigations.

Statistical linguistics studies the quantitative properties of language. Usage frequencies of acceptable or unacceptable linguistic structures are major objects of investigation. Therefore, the entire stock of linguistic frameworks is made use of at one point or another.

Mathematical linguistics studies mathematical properties of language, using concepts from fields such as algebra, computer science, and statistics, hence, wide usage of syntactic, phonological, and other linguistic frameworks.

Anthropological linguistics is the study of language variation and use in relation to the cultural patterns and beliefs of humankind, as investigated using the theories and methods of anthropology and referring to lexical, phonological, and discourse frameworks.

Applied linguistics is the application of linguistic theories, methods, and findings to the elucidation of language problems that have arisen in other domains. The term is especially used with reference to the field of foreign language learning and teaching, but it applies equally to several other fields, such as stylistics, lexicography, translation, and language planning, as well as to the clinical and educational fields. Since it covers a wide array of issues, it makes use of the entire linguistic framework.

Biological linguistics is the study of the biological conditions for language development and use in human beings, with reference both to the history of language in the human race and to child development. Syntactic, phonological, morphological, and lexical frameworks often lend themselves to biolinguistic studies.

Clinical linguistics is the application of linguistic theories and methods to the analysis of disorders of spoken, written, or signed language. Any linguistic framework may contribute to clinical studies depending on the topic of research.

Educational linguistics is the application of linguistic theories and methods to the study of the teaching and learning of a language, especially of a first language, in schools and other educational settings. Owing to its wide range of issues under investigation, the field of educational linguistics refers to any linguistic framework, depending on the circumstances of any particular study.

Ethnolinguistics is the study of language in relation to ethnic types and behavior, especially with reference to the way social interaction proceeds. Discourse, lexical, and pragmatic frameworks are of particular interest, but not exclusive to the field.

Geographical linguistics is the study of the regional distribution of languages and dialects, seen in relation to geographical factors in the environment. Phonological and lexical frameworks are particularly important to such studies.

Philosophical linguistics is the study of the role of language in the elucidation of philosophical concepts, and of the philosophical status of linguistic theories, methods, and observations. Pragmatic and discourse frameworks fall within the realm of these studies.

Theolinguistics is the study of the language used by scholars of biblical and other religious texts, by theologians, and others involved in the theory and practice of religious belief. The lexical framework lends itself to theolinguistic studies.

In conclusion, the overall field of contemporary linguistics itself provides an invaluable conceptual framework to a number of disciplines that cross-feed from its studies, findings, sources, concepts, and rules.

LINGUISTICS, HISTORICAL

Language change has been occurring as an aspect of human evolution throughout the centuries, serving as a sort of mirror reflection of human civilization and progress. The primary concern of historical linguistics is the study of language change. The central questions that historical linguistics raises are: Why do languages change? Why do certain languages die? How can we reconstruct extinct languages? How do borrowings from other languages affect the development of a language? Those questions will be addressed in what follows.

Such changes and development can be traced through all linguistic levels: phonetics, phonology,

morphology, syntax, and semantics. Moreover, as modern scientists claim, even discourse studies contribute significantly to the explorations of changes in the usage and pragmatic applications of certain grammatical and lexical constructions.

Different pronunciations of a word, different usages of words, the construction of new syntactic structures, the production of new linguistic units, and the disappearance of old versions all lend themselves to research in historical linguistics.

Linguistic change tends to occur when two equivalent forms coexist for a certain period and one form eventually gives way to another. As a consequence, one form disappears and another establishes itself in the language corpora. Historical factors such as territorial invasions, and hence language contacts, are often considered as driving forces of linguistic change. Additionally, with the development of trade, economy, technology, and intensification of social mobility, new lexical and phraseological units continually enter the language, new ways of pronouncing words are established, and new syntactic structures become fixed and more acceptable in any given language than the older ones.

Goals and Methods of Historical Linguistics

Among the primary goals of historical linguistics are to study the history of particular languages based on the existing written data; the study of prehistory of languages through comparative reconstruction; and the study of currently ongoing changes in the language that can be based on both written and spoken records and data. Through the study of these matters, historical linguists attempt to discover and formulate the general principles of linguistic change and identify the reasons for the transformations that languages undergo, both over centuries and at the time of study. Accordingly, historical linguists implement methodological principles of investigation that were proposed by Ferdinand de Saussure in the beginning of the 20th century and have been known as synchronic and diachronic linguistics since then. These methods of investigation, *synchronic* meaning observing changes in the present time and *diachronic* signifying language evolution through centuries, have been the fundamental principles in documenting linguistic

changes both historically and in the present time. Thus, it can be assumed that there is no single moment in which a living language is static and does not develop. The changes are ongoing, sometimes vividly and at others imperceptibly.

It should be noted that while the data of linguistic change from past centuries are relatively restricted because it is accessible only through written records, the data of present-day language development can be more diversified through written and spoken records. Modern historical linguists implement the various qualitative and quantitative methods of research and analysis, which may include interviews with informants, focus groups, participant observations, questionnaire analysis, online and live surveys, media analysis, and so forth.

It should also be borne in mind that it is not only the reconstruction of the past forms that is important for historical linguists, but interpretation, analysis, and cross-language comparison are of utmost significance for tracing certain regularities and patterns in linguistic changes.

Reconstructing a Proto-Language

One of the fundamental goals of historical linguistics is the reconstruction of proto-language that supposedly gave rise to the evolution of languages across the globe. Hence, the statement that the scientists make is that for all the differences that exist between languages, diverse languages might still originate from common proto-language. Therefore, the languages might be genetically related. Historical linguists present this statement most vividly through a family tree of languages that shows the connections of different languages to a common ancestor. Genetically related languages show common and recurrent correspondences in phonetic, lexical, or morphosyntactic structures. On the linguistic level, phonology and morphology seem to provide the most evident and illustrative data for historical analysis. Changes in sound systems and inflections are most frequently analyzed in the framework of historical linguistics to trace and establish genetic relations between the languages.

Reconstructing proto-Indo-European language, from which the majority of modern Euro-Asian languages derive, has been one of the most

fundamental landmark studies in historical linguistics conducted up to the present day. It should be noted at this point that such reconstruction does not lead to a primitive language. Reconstructed Indo-European language is a fully-fledged language, not a system of primordial grunts. A total of 8,000 years, or at most 10,000 years, is the furthest back that such type of reconstruction can take us to, and human language arose at least 80,000 years ago.

Several optimistically disposed scientists have gone as far as to reconstruct an even earlier language named *Nostratic* (Latin word meaning *our language*). According to the disputed views, *Nostratic* covers Indo-European; the Dravidian languages of India; the Kartvelian languages of the Caucasus; the Uralic family of languages, which includes Finnish and Hungarian; Altaic, which covers Turkish and Mongolian; and Afro-Asiatic, which includes Arabic and Berber. And some scientists have even taken a step further back and have put forward the idea of *Super-Nostratic* language, which links *Nostratic* to Arctic Indian languages in the north and to other African languages in the south. However, the idea of *Nostratic* and *Super-Nostratic* languages is controversial and requires further research and more valid evidence.

Typological Reconstruction

The most significant consequence brought about by the reconstruction method implemented by comparative historical linguistics is the elaboration of the typological reconstruction and especially the development of the subfield of typological syntax. The basic idea on which the method is based is the division and grouping of languages into basic types, each with its set of characteristics. English, for instance, can be categorized as verb-object (VO) language because it typically locates the object after verb. Depending on the syntactic structures predominant in a given language, it can be classified by language type; hence, the development of studies in typological syntax.

Typological reconstruction can also be applied to sounds, the most vivid example being the case of stop consonants [p, b, t, d] in Proto-Indo-European language, which are produced with a complete stoppage of airflow.

Thus, by historical reconstruction of a language, the detailed knowledge gained in the process of reconstruction can help the researchers to assign it to its corresponding type of languages. Identifying the type of language can provide further help in predicting the facts or characteristics for which there is no direct evidence.

Typological reconstruction is still a highly debated issue. There are no languages with fixed pure types. Most languages belong to a mixture of types owing to continuous fluctuations and alterations in the process of language development and evolution.

Tracing and analyzing the diffusion and spread of linguistic changes across different geographical areas is yet another newly evolving type of language reconstruction, which is still in the process of formation.

Language as a Constantly Changing Living Organism

One of the most fascinating ideas of language development and evolution was offered by Wilhelm von Humboldt (1767–1835), who perceived language as *energeia* (process, activity) and not *ergon* (end product of activity). Offering the deepest and most original insight into the nature of language, Humboldt thus presented language to humanity as a living and developing organism rather than a static compilation of forms and structures. He viewed language as an instant of speaking, an activity and not an inactive fixed form. Thus, Humboldt did not consider the study of a language's structure, its *Bau*, the ultimate end of linguistics. Because language in its fullest sense occurs only in the societal context in its acts of speech production and in what is being said through them, its true nature can only be explored and perceived in living discourse (*verbundener Rede*) and should be studied equally in its lasting manifestations in the works of culture and of science, in literature, poetry, and philosophy.

It is exactly this living nature of language that has permitted numerous scientists to conduct studies and explorations across languages and to come up with novel findings in language contacts and evolutionary processes, for it is through speech acts that linguistic forms tend to vary most

vividly and to constantly reintroduce novel meanings and forms.

Language Change and Its Causes

Language change is gradual and almost imperceptible. Historical linguistics mainly concerns itself with functional, psycholinguistic, and sociolinguistic explanations for language change. In reality, however, numerous other causes trigger language alterations over the course of centuries. The causes may range from random fluctuations in the usage of linguistic items to the natural and logical tendencies of humans to adapt linguistic usage and structures to evolving human speech apparatus and cognition.

Functional explanation views linguistic systems as self-regulating mechanisms that make languages more simpler, more symmetrical, and balanced. Phonological sound shifts, phonemic mergers, disappearance of homonymic words with conflicting meanings, and rectification of functional load (the number of functions a particular linguistic item has), all are subject to functional explanation.

Psycholinguistic explanation of change is concerned with cognitive processes going on in the human brain during the language acquisition process. Chomskyan principles of generative grammar that underlie the process of producing indefinite number of sentences using finite set of rules belong to the psycholinguistic explanation of change. The generation of novel types of syntactic structures and the disappearance of certain syntactic constructions could serve as illustrative examples in this respect.

The sociolinguistic explanation of change deals with the concepts of fuzziness and variation. *Fuzziness* implies the production of syntactic structures that are not quite grammatical, but are not totally ungrammatical either, meaning that individual speakers produce syntactic structures that do not strictly follow grammatical rules but that are not incorrect either. *Variation* implies the fact that speakers of a language have individual linguistic repertoires and use linguistic variables—different versions of linguistic items. The most illustrative examples could be speeches of different ethnic and social groups that produce linguistic items and structures idiosyncratic to them.

Alongside social variation, geographical variation of languages has been considered as one more contributing factor in linguistic change. It should also be mentioned that the linguist Edward Sapir noted in 1921 that linguistic drift (i.e., change) has a direction, meaning that the linguistic changes can be predicted and the direction of changes can be forecast. This directionality (mainly unidirectionality) principle has proved to be statistically significant and thus can serve as the basis for both linguistic evolution and language structure.

As a consequence of fuzziness and variation, certain linguistic items and structures disappear or become obsolete, while others spread widely and enter the corpora of a language. However, the concern that arises here is the basis upon which a construction will remain acceptable and spread widely and another one becomes regarded as unacceptable and disappears since there are no universally agreed restrictions and constraints on whether a certain linguistic item or construction is considered grammatically correct.

One noteworthy consequence that the study of language variations by historical linguistics has engendered is the establishment and wide use of the notion of linguistic variables—that is, sounds, morphological or syntactic elements, and lexical units that vary across times, social strata, and geographical areas, and that have been the objects of investigation in the field of statistical linguistics for a long time.

Sound Change

Probably the best-researched realm of historical linguistics is phonological change, which may take place both on the level of phonemes (phonemic change) and on the level of speech production (phonetic change). Sound change takes place when the ways of production of vowels or consonants change under the influence of the neighboring sounds. The basic assumption of comparative historical linguistics is that sound changes are consistent or regular rather than haphazard. Furthermore, if there are consistent sound correspondences between words with similar meanings in languages where borrowing can be ruled out, the correspondences cannot be due to chance. It can be, therefore, inferred that the languages concerned are so-called daughter languages descended from one

parent language. To illustrate the point, the following correspondence between English and Latin could provide a good example. Where English has *f*, corresponding Latin words with similar meanings have *p*, such as *father-pater*, *foot-pedem*, *fish-pisces*. When Romans arrived in Britain, the natives did not yet speak English, which was introduced at a later stage, so borrowing from Latin into English can be excluded. Consequently, the explanation of correspondences can lie in the fact that both Latin and English derived from one parent (proto) language that existed earlier.

The following sound change patterns can be identified: *palatalization* (fronting of the raised part of the tongue, e.g., mouse–mice, foot–feet); *velarization* (the movement of tongue backward toward velum or soft palate, e.g., English *sword* and German *Schwert*); *diphthongization* (changing of a simple sound into diphthong, e.g., house, ride from Middle English [u:] and [i:]); *monophthongization* or leveling of diphthongs before [ə] as in fire, tower, resulting in [fa:], [ta:]. Consonants can also change the manner and place of their articulation. The most common change pattern is *spirantization*, the change from stop to fricative (spirant), as was the case in Grimm's Law, when the Indo-European voiceless stops [p, t, k] became voiceless fricatives [f, θ, x] in the Germanic languages.

Phonetic change is most frequently conditioned by the specific phonetic environment that it occurs in. As an instance, the sound [r] was lost before consonants and word-finally—that is, court [ko:t], hair [heə]—but was retained in other positions—for example, hairy [heəri], right [rait]. Vocalization, disappearance, or weakening of consonants are yet further instances of sound changes.

The most widely spread type of changes that sound modifications lead to is *assimilation*, the partial or total adjustment or resemblance of a sound to another one, often the neighboring one, for example, im-possible, il-literate [m-p; l-l]. The word *assimilation* itself illustrates the point most vividly. It derives from the Latin word *as-similare* that through the assimilation process was derived from the earlier version *ad-similis* (meaning *like*).

A rarer case of sound change is *dissimilation*, whereby the neighboring sounds become partially or totally different, for example, pilgrim, Latin *peregrinus*.

Further instances of sound change are chain shifts, as in Grimm's Law, where the most illustrative examples are the change of Indo-European /p, t, k/ into /f, θ, x/, and /b, d, g/ into /p, t, k/. Another famous instance of sound change is the *Great Vowel Shift*, which involved the raising of long vowels, for example, /e:/ into /i:/, as in *meet*.

Grammatical Change

Grammatical change involves morphological and syntactic changes. As the second most frequent type of change after phonological change, the morphological change has facilitated the typological grouping of languages according to inflectional morphemic features. Hence, there exist isolating, agglutinating, and inflecting types of languages. In isolating languages (e.g., Chinese), words consist of single morphemes. In agglutinating languages, words consist of more than one morpheme, but each morpheme is formally separable and has a single meaning (e.g., Japanese). In inflecting languages, morpheme boundaries are often blurred, and several meanings can be accommodated in one form (e.g., Greek and Latin). In the process of linguistic change, languages can turn from isolating into agglutinating, and thereafter into inflectional. The cycle may as well repeat several times. Changes from isolating structures to agglutinating structures often happen in pidgins and creoles, where unstressed words often become prefixes and suffixes as a consequence of phonological reduction.

Modern English has lost most of its inflections and has turned from an inflecting synthetic language into an analytic language, in which fixed word order has substituted the former functions of inflections.

The most illustrative example of syntactic change is the development of tense forms through centuries. For instance, in Old English, there were only two tenses, present and past. Other tense forms developed later, most conspicuous opposition being simple versus progressive forms. In addition, questions and negatives were formed without the auxiliary verb *do* in Old English, for example, *I know not, whom trust you more?*

The types of syntactic changes fall under two major categories, reanalysis and grammaticalization, *reanalysis* implying the changes in word

order patterns in sentences (e.g., the development of SVO structure in English), and *grammaticalization* (or *grammaticization*), illustrating the development of tense categories (e.g., progressive forms), the development of main verb forms from auxiliary ones (e.g., the verb *will* acquiring the meaning of *want*), or the development of negative particles from negative intensifiers (e.g., not . . . a step). The term *grammaticalization* or *grammaticization* was coined by a French linguist, Antoine Meillet, who defined it as the attribution of a grammatical character to a previously autonomous word. The most illustrative case in this respect is the fact that verbs of *volition*, such as *want*, *wish*, and *desire*, have become the future markers; that is, have acquired the grammatical category of expressing the future.

Vocabulary Change

Several linguistic processes can be reflected in vocabulary change. These may include new word formation, word coinages, compounding (constructing one word from two independent words), affixation (adding prefixes and suffixes to a word to coin a new lexical unit), narrowing and extension of meaning (when a word loses one of its meanings or acquires a new meaning), amelioration (improvement of meaning, e.g., *knight* in Old English meant "boy, attendant") or pejoration (a negative evaluation of meaning, e.g., *silly* in Old English meant "happy, blessed"), production of new metaphors, metonymies, and so forth. Languages coming into contact with each other most frequently contribute to vocabulary changes. New lexical or phraseological units are often borrowed from one language into another. The new words often fuse into the host language through affixation or derivation that puts the loan words in the shape acceptable for the host language.

Borrowing a new word from another language that has a corresponding word in the native language may lead to the disappearance of one of those. Hence, the transformation of corpora takes place.

The reasons for vocabulary change in a language are various, meeting new communicative requirements being the most frequent ones. Furthermore, a psychological factor in vocabulary change is the attempt to avoid using taboo words and not to make direct reference to the unpleasant

or stigmatizing concepts and words. In addition, if the word usage wears off—if it is widely used and loses its expressive connotation—a new, more emphatic word enters the corpora and replaces it. Further instances of vocabulary change are related to the developments in science, technology, especially in fast growing and changing information technologies. The growth of trade, tourism, and of transnational business enterprises makes the process of vocabulary borrowings and linguistic interference even faster.

Relations of Historical Linguistics to Other Discipline

Historical linguistics has always been cross-feeding from other disciplines, such as geology, biology, statistics, and sociology. As early as the 19th century, the uniformitarian principle entered the realm of historical linguistics. Genetic linguistic relationships have been long displayed through the family tree model provided by biology. Furthermore, evolutionary biology has triggered discussions on language development and change and has consequently given rise to the new field of evolutionary linguistics, for which evolutionary theory has been the focal point. It perceives linguistic evolution as a progression from a more primitive to an ideally developed state of language that will be followed by decay and finally, lead to language death. Another view, however, puts linguistic evolution within the frame of natural selection, where random mutation leads to change. The role of genes and memes in replication and copying processes has also been adopted by evolutionary linguistics to trace the production and replication or decay of certain linguistic items and structures through time. Another important concept adapted from biology is the notion of *gradation*, which helps historical linguists arrange the linguistic forms and their changes in graded order (meaning not drastic or extreme alterations but changes organized in graded sequence). The aforementioned notion of *fuzziness* could serve as an example, implying that there are not totally incorrect or absolutely correct linguistic structures; rather, linguistic evolution constantly produces partially correct and partially incorrect items.

LOGIC, FORMAL AND INFORMAL

Mathematical logic aims at a universalist characterization of kinds of structural relationships that may be studied nonempirically. It thereby offers a resource for all fields, including the study of cognitive structures and semantic structures that constitute reasoning well. According to the logicist thesis espoused in Alfred North Whitehead

and Bertrand Russell's *Principia Mathematica*, mathematical logic is a field of its own—a field to which the various branches of pure mathematics, including geometry, all belong. Whether this is correct or whether mathematical logic is itself a branch of mathematics is an ongoing question much debated. In any case, it is clear that many different structures may be studied, and among them are what are called *deductive logics* (e.g., classical, intensional, modal subjunctive [counterfactual], intuitionist, relevant, paraconsistent), each offering axioms and/or inference rules of transition (based on syntactic *formal* features alone) meant to capture all and only those well-formed formulas (WFFs) that are *valid* (i.e., preserve a fixed distinguished value under all *admissible* interpretations).

Informal logic endeavors to explain and teach real-life argument practices that are regarded as *good* by the standards that are used as paradigms in various fields. The notion has been understood and interpreted in a variety of different ways, and its connections with formal logic are often debated. Over the years, diverse disciplines have endeavored to provide it a proper home under each discipline's conception of what constitutes reasoning well in general—using its own field more or less as a paradigm. The presentation of informal logic may take different forms as it becomes tailored to applied disciplines such as cognitive (and developmental) psychology, evolutionary anthropology, and law. Various textbooks offer many pedagogical innovations drawn from a wide array of fields such as applied probability and statistics, economics, cognitive psychology, linguistic semiotics, speech communication, and rhetoric; and may also include doctrines of historicism and historical materialism. Considered in this way, the field of informal logic is a multi-disciplinary attempt to develop an argumentation theory that endeavors to give an account of what constitutes real-life good reasoning. This entry first explores the traditions within which logic itself has been defined and then continues with an extended discussion of the distinctions between the nature and methods of argument of formal and informal logic, including explanations and examples of the various approaches, analytical methods, and arguments of rival schools up to the present day.

One Hundred Definitions

The philosopher, logician, and mathematician Charles Sanders Peirce (1839–1914) amusingly suggested that nearly one hundred definitions of *logic* may have been tried, but he thought it had been generally conceded that logic presents the methods and principles that distinguish good from a bad argument (reasoning). The Scottish philosopher David Hume (1711–1776) had famously contended that reason is the slave of the passions—that is, a tool for successful means–end calculations. Its value lies, thereby, in its success in guiding one to achieve one's goals, and good reasoning is the best avenue. But this view of the nature of reason remains controversial, and Immanuel Kant (1724–1804) famously held, contra Hume, that it is reason that sets goals and determines worthy values.

When reason is viewed as an evolved set of cognitive faculties for engagement, logic is viewed as being within the province of (evolutionary) psychology. This is the pragmatist view of John Dewey (1859–1952), for whom the field of *logic* (whether formal or informal) endeavors to discover and improve the behavior patterns of human cognitive inference that have evolved because of the adaptive advantages they conferred on the species. Reasoning poorly, especially the common mistakes in applied probability, is thereby diagnosed in terms of behaviors that are a hold-over from the natural evolutionary history of the brain.

William James (1842–1910), who with Peirce originated philosophical *pragmatism*, put no emphasis at all on viewing the methods of good argumentation as something abstractly tracking truth and fact. This is usually regarded as its Achilles heel. Obviously, the most fallacious arguments may, sadly, enjoy an interval of practical success—especially if *success* can be measured with respect to a community caught up in the dogmatism of an age. A careful pragmatist may address this by defining “good reasoning” as the ideal kind of reasoning that results from an *unencumbered* practice of trial and error. Defining *idealization*, however, will require the mathematical logic of *limits*, and such abstract mathematical notions remain difficult for pragmatism and evolutionary psychology to embrace. Moreover, success at the limit of idealized practical engagement still cannot secure truth. The pragmatist responds by offering a notion of *truth* as whatever it does is secure.

Peirce and James wrote before (or near) the dawn of mathematical logic, which altered the debate significantly, subsuming at least part of mathematics itself into the domain of its new conception of *logic*. However, there remain rival traditions within mathematical logic itself. On the algebraic tradition, deductive logic began with Aristotelian categorical forms:

A: All S are P E: No S are P

I: Some S are P O: Some S are not P

It studied the syllogism and offered rules governing *immediate inference* such as contraposition (switch S and P and complement each), obversion (change quality, universal $\Leftrightarrow$ particular, and add a complement to P), and inversion (switch S and P). Subsequent medieval scholastic studies introduced propositional connectives, and endeavored to distill quantifier scope to block fallacious inferences from “I owe you a donkey” to “some donkey is such that I owe it to you.” The invalidity of a syllogism was thought to consist in it having a counterexample with substitutions for S, P, and middle term M. Thus consider:

All P are M; All S are M; Therefore, Some S are P

This is shown to be invalid by appeal to:

All cats are animals; All dogs are animals
Therefore, Some dogs are cats

The accepted counterexample makes the premises true and conclusion false.

Algebraic approaches far transcend what an Aristotelian can accomplish with categoricals. It began with the work of George Boole (1815–1864) and with Peirce and Ernst Schröder’s *Algebra of Logic*, which endeavored to combine algebras of operations to which *and*, *or*, and *not* can be associated (product, sum, inverse) with quantifiers understood as (possibly infinite) product and sum. Booleans and set theorists removed the Aristotelian restriction that A, E, I, O forms apply only when the categories are not empty. Modern-day studies in formal logic emphasize the algebraic tradition, focusing on valuation tables (i.e., truth-tables) for determining validity (understood as preservation of a distinguished value) and quantification theory with identity. The algebraic tradition presents an algebra of fixed operations. Validity no longer

relies on an appeal to substitution counterexamples but is determined by considering algebraic rules or Venn diagrams picturing the premises without the conclusion. This begins the separation of the field of logic from anything empirical. It frees logic from all considerations of the psychology of inference and the pragmatics of success. But it accepts the Humean barb that in any deduction (as opposed to induction) the conclusion cannot bring forth any content not already in the premises.

The rival tradition in mathematical logic originates with Gottlob Frege (1848–1925), who rejects the algebraic approach with its fixed operations. Frege made the study of operations merely one of a great many applications of his logic of functions, which investigates *a priori* (without empirical investigation of nature) structural features of relations between functions but also assures the existence of ever new functions themselves. In Frege’s logic, one discovers the fact that every relation has a converse, but that the converse of a function may not itself be a function. (The trigonometric *sine* of an angle is a well-known example.) This discovery, abstract as it is, should guide one’s practical inference—if good practical inference aims at *truth*. You may love but one, but you’ll behave ignorantly if you conclude that your beloved cannot be loved by a rival. It remains improper as a conclusion even if it happens (by some sheer contingency) to be successful. No feature of psychology, evolution, social practice, history, and so on, is the least bit relevant.

A Fregean nonempirical tradition in mathematical logic allows for the discovery of ever new functions, and thereby the Humean barb is rejected. A deduction’s conclusion may well contain new information not obtainable by the algebraic process of manipulating the operations given in the premises.

The tradition finds the notions of *number*, *successor*, *infinite*, and *finite* to be purely quantificational notions concerning relations. Fregean logic assures the existence of relations involved, for example, in the assertion that for any one-to-one relation *R* whose relata are correlated with a group of exactly 5, there are groups of exactly 2 and 3 and a relation *S* isomorphic to *R*. (For example, digits on my left hand are correlated one-to-one and onto the digits of my right hand—namely, the group of thumb and forefinger, and the group of middle, ring, and pinkie.) There is no known bridge between the Fregean and algebraic

traditions *within* mathematical logic, and quite different philosophies of mind, rationality, and reason have grown up around each—with those connected with the Fregean more rationalist and those surrounding the algebraic distinctly empiricist.

Deductive Logic (Informal vs. Formal)

Informal logic has the mission to “study real-life argument.” This can take many different forms and involve eclectic methods borrowed from several fields. The general methods of argument analysis explore aspects of burden of proof, norms governing style (in specific fields such as law, politics, empirical scientific research) and may include historical, social, libertarian, neoliberal, antiliberal, feminist, and historical materialist points of view. It points out complex assumptions (philosophical, epistemological, social-political, etc.) that may lurk behind premises but are not explicitly mentioned in premises of any real-life argument.

What, then, is the practical value of formalism? In deductive formal logic, one works with the formalisms themselves, and the rules of transition are based solely on the formal syntactic features. Formal logic may draw attention to the challenging practice of transcription from natural language to formal notations. In this respect, the formal logician is not disagreeing with the informalist. The disagreement arises because the formal logician holds that transcription is *required* for the evaluation of a deductive argument’s being *valid*—since *validity* in (for example) quantification theory is understood as a feature arising from the structure that is given by *and*, *or*, *not*, *all*, and *some*. (Any admissible model of its premises thereby models its conclusion.) To illustrate, consider:

This argument is valid; Therefore, the cat is on the mat and the cat is not on the mat.

According to the formalist, in order to assess the validity of the above argument, one must first transcribe it to determine its logical form. If one doesn’t do this, a danger looms. One might find no counterexample, wherein the premise is true and the conclusion false. One might erroneously conclude that the argument is valid! But then its contradictory conclusion should be true; we get a paradox. The formalist’s demand to know the

structure of the argument diagnoses the mistake. Suppose it is this:

q ; Therefore, p and $\sim p$

The formal logician concludes that the deductive argument is simply invalid.

The transition (inference) rules governing $\bullet$, $\vee$, $\sim$ (*and*, *or*, *not*) are the foundation of the De Morgan’s rules governing the operations $\cap$, $\cup$, $\sim$ (*intersection*, *union*, and *complement*). Using $\Leftrightarrow$ for transition:

$$S \cap P \Leftrightarrow S \cup P \quad \sim(p \bullet q) \Leftrightarrow \sim p \vee \sim q$$

$$S \cup P \Leftrightarrow S \cap P \quad \sim(p \vee q) \Leftrightarrow \sim p \bullet \sim q$$

The ideas are given by our natural understanding of *and*, *or*, *not*, and it is these that give rise to the operations. Consider also quantifier negations:

Not all S are $P \Leftrightarrow$ Some S are not P

$$\sim(x)(\sim Sx \vee Px) \Leftrightarrow (\exists x) \sim(\sim Sx \vee Px)$$

No (i.e., not some) S are $P \Leftrightarrow$ All S are not P

$$\sim(\exists x)(Sx \bullet Px) \Leftrightarrow (x) \sim(Sx \bullet Px)$$

The quantifier and De Morgan’s transition patterns are natural.

For quantification, the mathematics of *sum* and *product* of the Peirce–Schröder *Algebra of Logic* proved tedious and clumsy in practice, and the Whitehead–Russell (W–R) notations became widely adopted instead. We now have:

Aristotle	Set (Venn)	W–R
A: All S are P	$S \cap P = \emptyset$	$(x)(\sim Sx \vee Px)$
E: No S are P	$S \cap P = \emptyset$	$\sim(\exists x)(Sx \bullet Px)$ i.e., $(x) \sim(Sx \bullet Px)$ i.e., $(x)(\sim Sx \vee \sim Px)$
I: Some S are P	$S \cap P = \emptyset$	$(\exists x)(Sx \bullet Px)$
O: Some S are not P	$S \cap P = \emptyset$	$(\exists x)(Sx \bullet \sim Px)$ i.e., $(x) \sim(Sx \bullet \sim Px)$ i.e., $(x)(\sim Sx \vee \sim \sim Px)$ i.e., $(x)(\sim Sx \vee Px)$

The power of the W–R transcription is nicely illustrated in its ability to easily capture the following:

All A are B ; Therefore, all heads of some A are things that are heads of some B .

$$(x)(\sim Ax \vee Bx); (x)(\sim (\exists y)(Ax \bullet Hxy) \\ \vee (\exists y)(Ax \bullet Hxy)) \cdot$$

No categorical treatment of this argument is workable.

The great benefit of formalism is that no ambiguities can arise. Real-life negations, predications, quantifications, conjunctions, and disjunctions can be very difficult because they are often expressed in many different and often misleading ways in natural language. A colloquial way to say

“Not all snakes are poisonous.”
is to say, with a tone of voice:

“All snakes are not poisonous.”

One must be on the lookout for such poetic (if you will) devices. Informal logic addresses itself to this. The study of real-life natural language modes of expression is very important, but not a rival to formal logic emphasis on structure. Indeed, it is guided by it.

Consider the following formal pattern of the immediate inference that is *Contraposition* (the second of which is parameterized):

All *S* are *P* $\hookrightarrow$ All *P* are *S*

All *A* and *S* are *A* and *P* $\hookrightarrow$ All *A* and *P* are *A*
and *S*.

Parameterized immediate inference is what often occurs in natural language cases. We don't use:

All life forms indigenous to the Andromeda galaxy are silicon-based life forms.

Therefore, All non-silicon-based-life-forms are
non-life-forms indigenous-to-the-Andromeda-galaxy.

The proper contraposition is:

All life forms not silicon based are life forms not
indigenous to the Andromeda galaxy.

Knowing the formal pattern is quite illuminating. Natural language complements can be challenging. Because of the many styles and meanings of negation, false complements abound. For example, *not believe* does not mean *disbelieve*, *inhuman* does not mean *not human*, *not proved* does not

mean *disproved*, and *unhappy* does not mean *not happy*; whereas *unintelligible* does mean *not intelligible*. Note that *not valid* does not mean *invalid*. *Valid* and *proof* are technical notions of formal deductive logic. Only a deductive argument that is not valid is properly said to be *invalid*. Every inductive argument fails to be valid. That is not a fault since it wasn't purporting to be a deduction. Empirical theories such as evolution by natural selection are not proved, but that is not a fault, because proof is not sought and belief is warranted by a wealth of corroborating evidence in their favor.

Informal logic often focuses on fallacies of reasoning (both formal and informal). Some schools of informal logic go so far as to argue that there are successful cognitive operations that are the victors of the processes of natural selection. In this school, controversies over whether such cognitive operations might be successful and yet widely depart from truth is not the focus of attention. Instead, it is the norms of acceptance within a field that is the focus. But other schools of informal logic do not agree that paradigms of good reasoning in the various fields are the proper arbitrators. Such schools endeavor to preserve the thesis that *poor reasoning* is distinctive in its failure to capture truth and fact.

Natural language makes it challenging to parse negations and double negations. Formal characterization eliminates any chance of ambiguity. This suggests that the study of formal and informal fallacies may be best understood as simply the study of the myriad ways of confusion due to equivocations arising in natural language. Whether it is applied deductive logic, applied inductive methods, or even applied mathematics and physics, the kinds of equivocations and confusion that arise due to ambiguities of natural language uses of *and*, *or*, *not all*, and *some* can be enormous. We have the ever-popular example: “Jack and Jill went up the hill.” But this is not the *and* of conjunction. They went up the hill together in consort with one another. It does not mean Jack went up the hill *and* Jill went up the hill.

Consider the case of the formal fallacy of *Affirming the Consequent*. It is simply a problem of confusion due to equivocation. Consider the Disjunctive Argument patterns:

Either *p* or *q*; not *p*; Therefore *q*.

Either not *p* or *q*; *p*; Therefore *q*.

The letters p and q stand in for declarative statements. Admittedly, by making mistakes about whether one has a genuine double negation in the natural language, one might misapply the disjunctive argument patterns. That is a case of equivocation. Now the expression “Either not p or q ” can be clumsy, and logic books often stipulate that “If p then q ” will conveniently be used as a substitute. With the stipulation, we get:

If p then q ; p ; Therefore q .
i.e., Either not p or q ; p ; Therefore q .

It is difficult to imagine someone reasoning with:

Either not p or q , q therefore p .
i.e., If p then q ; q ; Therefore, p .

However, if equivocation is at play, one might well reason with:

Events of kind q are (very typically) caused by events of kind p ; q ; Therefore (very likely) p

This reasoning is inductive. The mistake lies in conflating the natural language “if ... then,” which may express causal ties, with the stipulated “if ... then” of the logic books.

Ambiguities also infest the use of “if ... then” because it may convey a subjunctive. We have:

If p were then q would be. $p \Box q$.

Consider the following:
 No student would have passed were they to goof off.
 $\sim(\exists x)(Sx \bullet (Gx \Box Px))$

Compare this:
 Every student would have failed were they to have goofed off.
 $(x)(\sim Sx \vee \sim(Gx \Box Px))$

The formalisms are logically equivalent, but the English of the second is ambiguous and might mean:

$(x)(\sim Sx \vee (Gx \Box \sim Px))$.

Equivocating, one may be misled into thinking we have:

$(x)(\sim Sx \vee \sim(Gx \Box Px)) \not\equiv (x)(\sim Sx \vee (Gx \Box \sim Px))$.

Obviously, equivocation does not support belief in the law and inference of conditional excluded middle:

$(p \Box q) \vee (p \Box \sim q)$
 $\sim(p \Box q) \not\supset (p \Box \sim q)$

The formalisms make the error clear, where the English struggles. Thus are some of the benefits of formal logic working in collusion with informal logic.

Are there really *Formal Fallacies* that are committed by untrained reasoners or just various ways of equivocation? Consider the formal fallacy of *Begging the Question* whereby the conclusion is asserted in one or another premise. A good case is:

Action a is a murder; Therefore action a is wrong.

By definition, “ a is a murder” means “ a is wrongful and a is a killing.” Thus, the conclusion is asserted in the premise. It is only equivocating on the meaning of *murder* that one might fallaciously think that the argument was informative. Note that the premise, in this case, asserts a conjunction, which by its nature asserts each conjunct. The following is not a case of begging the question:

Everything is physical; e is an electron; Therefore, e is an electron and e is physical.

The conclusion is not asserted by the premise but is, instead, such that any model of the premise models the conclusion. Any instance of the deductively valid argument form

p ; Therefore p

is an argument that begs the question. But the fallacy of thinking such an argument to be informative seems to arise only via equivocation.

The *Gambler's Fallacy* is another case. Each time one flips an idealized fair coin the mathematical probability of it being Heads is $\frac{1}{2}$. But what is the probability, after, say, three flips, none being Heads, of the fourth flip being Heads? The answer still is $\frac{1}{2}$, at least on one interpretation of the question, for the current flip event is not impacted by the past. The gambler, however, may remark: “But surely Heads is more likely *now*.” What is at work in the gambler's misguided thinking? There is an ambiguity in the meaning of *now* as used

here. What is the probability in four flips of a fair coin (which is the same as one flip of four fair coins) that *none* should be Heads? Answer 1/16. The fallacy here is equivocating on the import of *now*, and thereby conflating two different events with distinct probabilities.

Perhaps a most intriguing case of a formal fallacy is illustrated by the *Conjunction Fallacy* (Linda Paradox), of Amos Tversky and Daniel Kahneman, which allegedly infests ordinary uses of the notion of *probability*.

In college (in the 1980s during the heyday of the feminist movement), the woman Linda was deeply concerned with such issues of discrimination and social justice, and she participated in demonstrations. Which is more probable:

- (a) Linda is a bank teller
- (b) Linda is a bank teller and is active in the feminist movement.

In empirical studies, most participants chose (b) in striking violation of the mathematical probability law that $\text{Prob}(A \mid B) < \text{Prob}(A)$. That anyone would commit such a fallacy seems shocking. Researchers have disagreed about whether the explanation concerns an evolved cognitive weakness in thinking about probability by thinking of *representative* cases based on parochial experience—that is, of women of the day—rather than applying abstract mathematical or frequency or physical propensity notions of probability. But at least one school, as made clear in Hertwig and Gigerenzer (1999), faults the experimental methods, noting ambiguities in the question's framing and wording. Perhaps (a) was interpreted by participants to mean:

- (a)*: Linda is a bank teller and *not* active in the feminist movement.

If so, then most participants got it right. Research in informal logic reasoning must endeavor to avoid infestation of such experiments by equivocation and confusion.

Equivocation is rightfully salient among the informal fallacies that informal logic draws special attention to. It may well also be at the heart of the common *Informal Fallacies*? Typical categories of fallacies given in informal logic include the following: *Fallacies of Relevance* (pity, ad populum,

ad hominem, accident, straw person, non-sequitur, red herring); *Fallacies of Weak Induction* (unqualified authority, ignorance, false cause, hasty generalization, slippery slope); *Presumption Fallacies* (begging the question, complex question, false alternatives); *Fallacies of Ambiguity* (equivocation, amphiboly); and *Whole-Part Fallacies* (composition, division). All admit that it is not clear whether a perfectly justified classification scheme can be found.

Whole-Part Fallacies notoriously equivocate on the wide variety of meaning of *part*. A member is not a part of a class in the same sense that a piston is part of an engine, a governor is part of the State government, a chromosome is part of a cell, a finger is a part of a hand, and a galaxy is part of the universe. Consider the famous informal fallacy Ad Hominem, whereby one allegedly evaluates an argument by criticizing the character (and/or associations) of the person giving it. Perhaps what really happens is triage—deciding inductively that if a person has a sordid history of giving (or belongs to an association that gives) bad arguments intended to deceive, the current one (on a relevantly similar topic) is likely also to be bad. Unjustified triage ought to be avoided, but it is not a fallacy. Is there a fallacy of Appeal to Pity whereby one questionably evaluates an argument to a conclusion (say guilt or nonguilt of a defendant) simply by one's being justified in having pity over the miserable state of those concerned? Appeal to the pitiable state might well give good grounds for practical action (e.g., lighter sentence for the convicted), but that simply changed the issue entirely. Equivocation is again at work here as it is in the fallacy of Appeal to Force, whereby the notion of a *reason to believe* can mean expedience to bring oneself to believe (say, to stay alive) as opposed to meaning to bring about a belief *based on the evidence*. It begins to look as though a great many of the so-called informal fallacies are ways of equivocation. If that is the case, it is a very worthy topic of study for informal logic and it requires on-the-ground, real-life investigations to understand the many ways.

Informal logic should not be confused with *inductive logic*, which studies such topics as statistics, expected utility, Bayesian theory, and probability (mathematical, causal/propensity, frequency, degree of credence). Statistic and probability theory

are applied mathematics. Bayes' theorem, after all, is a theorem of pure mathematics. Applying it, however, can be quite a complicated matter of discerning whether there is genuine independence of events, and properly recognizing how orderings are required for infinitary as opposed to finitary probability spaces. All the same, applications require transcriptions into formal mathematical apparatus, and it is here that confusions produced by natural language often arise. Informal logic has just as significant a role to play when it comes to errors that can arise in transcriptions involving applied mathematics, probability theory, applied statistics, and so on—even applied physics. Its role here, however, seems no different from its legitimate role in the study of how natural language ambiguities may infest applications of formal theories.

LOGIC, INDUCTIVE

Logical arguments are generally categorized as either inductive or deductive. Induction can be defined as a process for moving from particular instances to general statements or conclusions. It starts with a number of singular statements based on specific instances of an event. Based on these statements, a general conclusion is made. It is a method that helps us move from particular facts or observations to general statements that comprehend them. It is, therefore, used to generate theory from data. It is often seen as the opposite of deduction. This entry describes the nature of inductive logic and provides a historical account of its origins in ancient Greece and its subsequent development. Next, the major critiques of the inductive method are presented, followed by responses from its supporters, and the entry concludes with a review of the ways in which induction has been used in the domain of the social sciences.

One important aspect of inductive logic is that observations of the natural world need to be performed objectively and systematically. Observations that are made through our senses should not be guided by preconceived ideas or assumptions.

Generalizations are made based on these observations, and such generalizations can be strengthened by further observations. Therefore, a theory to explain a phenomenon is formulated on the basis of generalization made using specific observations. One common example used to explain induction is the observation of ravens. If every raven that has been observed so far is black, we will be led to draw a conclusion that all ravens are black.

Scholars and philosophers have described in various ways the principles or steps in induction. Carl Hempel and Anthony O'Hear have identified four main stages in induction. The first step involves the observation and recording of facts. This is followed by careful analysis of these facts without being guided by any hypothesis or preconceived ideas. Generalizations are then made on the basis of the analysis of the observations, and finally, these generalizations are tested further.

Rom Harré has explained that the three principles of induction are accumulation, induction, and instance confirmation. The principle of accumulation refers to the view that knowledge grows through accumulation of attested facts, which does not alter previously known facts. The principle of induction emphasizes that inference of universal laws can be done on the basis of accumulated facts. Statements from observations and experiments can be used to infer a general law. The third principle explains that our belief in a law depends on the number of positive instances that have been observed. For example, the more black ravens we observe, the more willing we will be to accept the finding that all ravens are black.

Induction, particularly Baconian induction—a method developed by Francis Bacon (1561–1626), one of the founders of modern science—represents a popular conception of science and what scientists do; namely, rigorously making observations and conducting experiments. Through meticulous analysis of the data that have been collected, they produce new discoveries. Baconian induction starts with the process of making observations that are free from three idols, so called. The first of these, *idols of the tribe*, refers to the inclination to see more regularities in nature than there actually are. The second, *idols of the cave*, refers to personal weaknesses based on our likes and dislikes. The third, *idols of the marketplace*, refers to

the confusions that arise from our language and terminologies.

In Baconian induction, the idea is to gather information regarding a phenomenon that allows us to move from particular observations to a general conclusion. According to Bacon, generalizations from particulars to universals need to be made in an orderly manner. The Baconian method of induction starts with observations. These observations are then generalized to a lower level axiom. Gradually from these lower level axioms, one can move up to a universal generalization, which he considered the goal of scientific inference. This, together with focusing on positive and negative instances, will help to avoid hasty universal generalizations. He also argued that experiments are important in scientific discoveries because they allow us to control the conditions of observations. Observing a phenomenon without any control would limit the depth of one's observation. By conducting experiments, researchers are able to manipulate conditions and observe how these conditions affect the phenomenon being studied. This would not be possible without performing experiments.

Baconian induction presents an ideal scientific method that is designed to be free from bias and fully based on objective observations. This was extremely important, especially at a time when many theories were influenced by philosophy or religious beliefs. It was a way of ensuring that theories were empirically sound. In reality, this is not necessarily how many scientific discoveries have been made. Even though many theories have been built inductively, many were not or could not have been discovered in this manner. In addition to this, as some scholars have noted, intuition may play an important role in scientific discoveries.

Origins and Development

Aristotle (385–332 B.C.E.) is considered the first thinker to describe inductive logic. His form of inductive reasoning was called *enumerative induction*, whereby knowledge is produced from a limited number of observations.

Bacon, as noted above, was the first major philosopher who explained the method of induction, which is still regarded by many as the scientific method. The Baconian method was stated in his

Novum Organum, which was published in 1620. Bacon suggested a more complex and gradual process of moving from particulars to generalizations and rejected the Aristotelian methodology of syllogistic demonstration. Bacon argued against the process of simply accumulating knowledge by generalizing from observations. He felt that such generalizations do not have applicability beyond the observed instances. His is an eliminative method of induction and emphasized the importance of focusing on negative instances. Negative instances are important to avoid a hasty generalization based only on positive instances. In making observations, it is important to identify elements that are present in positive cases, absent in negative cases, and vary accordingly in other cases. After making such observations, an accurate conclusion can be drawn. Bacon argued that focusing on both positive and negative instances stops one from jumping to conclusions from a limited number of observations.

Bacon demonstrated this type of scientific procedure through his investigation of the nature of heat. The investigation of heat can be done by collecting instances of heat and collecting information regarding the characteristics of each type of heat (e.g., rays of the sun, fires). These are seen as the positive instances. The next step is to gather instances that are in some manner similar to these instances but are not considered as heat (e.g., rays of the moon, starlight). These are called the negative instances. We also need to look at other instances with various degrees of heat. After looking at all the characteristics that are present in the positive instances, absent in the negative instances, and vary with the varying degrees of heat, a conclusion can be reached regarding the nature of heat.

Two centuries later, John Stuart Mill further elaborated the process of induction by stating what is called *Mill's canons of induction*. The canons are elementary experimental methods to identify general laws by identifying causes and effects of a phenomenon. The fundamental principle of induction is the proposition that the course of nature is uniform and the purpose of science is to discover causal laws. There are five canons of inductions, namely, the *method of agreement*, the *method of difference*, the *indirect method of difference* or *joint method of agreement and difference*, the

method of residues, and the *method of concomitant variations*.

Based on the method of agreement, in an investigation if at least two instances of the phenomenon have only one circumstance in common, then that circumstance is the cause (or effect) of the given phenomenon. In the case of an instance when the phenomenon under investigation happens and in another instance when it does not occur and all circumstances are the same except one, the missing one is the cause or the effect of the phenomenon. This is called the method of difference. The third canon combines the method of agreement and difference. When there are a few instances when the phenomenon occurs and it has only one circumstance in common and a few instances when it does not occur and the common circumstance is not present, that circumstance is understood to be the cause or the effect of the phenomenon. The fourth canon, the method of residue, is based on previously established cause and effect. If we have established from previous induction the cause of some aspect of the phenomenon, then what is left will be the cause of the remainder of the phenomenon. The final canon, the method of concomitant variations, emphasizes the connection between two phenomena. When one phenomenon varies together with another phenomenon, one will be the cause of the other.

Critique of Induction

The Scottish philosopher David Hume (1711–1776) is one of the first inductive sceptics. The problems he highlighted on induction were profound and received much attention from many philosophers even though he did not use the term induction in his argument. His arguments were mainly against the use of induction to establish causal relations. He highlighted that the major problem with induction is the difficulty in justifying the process of induction via either a deductive or an inductive argument. Even though we often use our experiences to make inferences in everyday life, Hume believed that induction cannot be justified rationally. Using past successes of induction to justify the use of induction puts us in a circular argument. Inductive inferences cannot be justified logically because there is no clear logic to show how one moves from observations to

generalizations. Therefore, one cannot claim that theories are not directly derived from data because these theories are explanations invented to account for the collected data.

Subsequently, critics have argued that there is no logical way of establishing the validity of the generalizations made through induction because induction involves the process of making generalized statements from a finite number of observations. In induction, we are using finite observations to generalize on infinite unobserved objects. Induction involves a process of making a claim beyond the mere observations. The conclusions reached on the basis of observations may be true for the observations that have been made, but there is no guarantee they will be applicable to future observations. Generalizations concerning unobserved objects, or the future, can only hold true if we depend on the principle of uniformity of nature, and this principle has not been proven empirically. Our senses are able to confirm what has been observed in the past, but there is no way of knowing how the same phenomena will look in the future. Therefore, we are making generalizations based on an assumption that has never been proven. Going back to the example of the ravens, even if all the ravens that have been observed so far have been black, there is no assurance that the next raven to be observed will be black. There is no way of guaranteeing this unless we are able to make all possible observations related to a phenomenon, and this will never be possible.

The second major criticism relates to the number of observations used in induction. Because it is impossible to make all possible observations, there is a need to decide on the number of observations that are necessary to make generalizations. Even if we decide only to make observations that are relevant to our study, there is still a need to decide on which observations are relevant to the study. In order to make the investigation manageable and practical, researchers are forced to decide on what to observe and how much to observe. This brings us to the next problem of induction, which relates to objective observations.

Objective observations are observations that are made without any preconceived ideas as to what the relevant observations are. It is believed that preconceived ideas about observations will introduce bias and jeopardize the objectivity of

scientific enquiry. Carl G. Hempel argued that such a narrow conception of induction will not allow scientific investigations to be carried out. Even if such an investigation is started, it would be almost impossible to collect all facts without any preconceived idea regarding the facts or observations. If, for example, one would like to study sand, is it possible to observe every grain of sand or every characteristic of sand? Karl Popper argued that it is impossible to start a scientific investigation without some sort of theory or idea regarding the investigation, which will guide the observations made by scientists. Even if objective observations are possible, many inferences can be made from the same observations and all can be equally correct. So how does one decide which generalization is accepted while which is rejected? Related to this, Nelson Goodman adds another problem with induction that he refers to as the problem of *projectability*. He emphasizes the difficulty in generalizing from past observations because there is no guarantee that the future will resemble the past. In addition to this, there is no clear way of distinguishing what is considered a confirmable generalization with a nonconfirmable or accidental generalization. He explained that although seeing another black raven can help confirm our generalization that all ravens are black, seeing a man who is a third son in a room does not confirm that all men in that room are third sons or that a man we would see in that room the following day will be a third son. The former is an example of a lawlike statement, while the latter is an example of accidental generality. Goodman differentiated that an accidental generalization often involves spatial and temporal restrictions (e.g., people in a room), whereas a lawlike generalization concerns complete generality (e.g., all ravens). Even though complete generality is a sufficient condition for lawlikeness, he also highlighted that it is often not easy to define complete generality. This he called the *new riddle of induction*.

On another front, Rom Harré argued that the growth of science happens not merely by the accumulation of facts or data by scientists as suggested by inductivists. The growth of science happens through the accumulation of facts and advancement in theory. Therefore, the explanation of a phenomenon cannot be achieved merely by

establishing patterns based on a finite number of observations. These observations may help to explain patterns of association but may not be able to provide an explanation on how these patterns occur. Furthermore, scientists have emphasized that many discoveries are made with the help of intuition. There are also some discoveries that occurred accidentally.

Justification of Induction

Since Hume's critique, many philosophers have tried to justify induction. Among them are Hans Reichenbach, Frederick L. Will, Peter Strawson, Bertrand Russell, and Jin Yuelin. They used various ways of justifying induction.

Reichenbach offered a pragmatic justification for induction. He accepts that induction cannot be justified inductively and deductively but questions whether it is necessary to have a justification of induction in order to accept that its conclusions are true. For him, while our ability to prove the truth of a conclusion will justify induction, such justification does not necessarily prove that the conclusion is true. Therefore, the proof that the conclusion is true is only a sufficient condition for the justification of induction. He believed that induction is the better way of reasoning based on experience compared with any other method of finding the truth. He uses the analogy of a cancer patient to emphasize his point: The patient will die unless the patient undergoes an operation. While there is no guarantee that the operation will be successful, it is the patient's only hope of survival. Therefore, the patient will choose the surgery because that is the best bet to survive. Similarly, Reichenbach believed that induction is our best bet and if there are laws of nature and we follow them, we can, to some extent, predict the future. Reichenbach's view has been criticized on the grounds that it is not an epistemic justification and does not give a reason to believe that induction is indeed true.

Peter Strawson gives a dissolution argument to justify induction. He argues that the demand for justification of induction is improper and a misunderstanding of induction. He rejects the idea of deductively justifying induction. According to him, if inductive argument is proved to be deductively valid, then it would be a deductive argument. This he finds absurd and stresses that induction must be

assessed using inductive standards. He disagrees that induction is justified by its success but says that a successful recipe for drawing conclusions regarding the unobserved must be one that has inductive support. The more success we have by repeating a recipe is the evidence we have in its favor.

Bertrand Russell maintains a contradictory position in relation to induction. While he accepts Hume's problem with induction, he also acknowledges that the importance of habit, knowledge, and common sense based on induction are rather reliable. He agrees that certainty may never be met through induction. He explains in his principle of induction that probability is the main aim of induction. If A is found to be associated with B, the more cases that show the association between A and B, the higher the probability A is always associated with B. After a certain number of observations, this probability moves closer to certainty. He argues that probability is always dependent on data. Additional data can alter the probability of an event. He uses the example of white swans to explain this point. If all swans that have been observed so far are white, it is probable that all swans are white. When a black swan is observed, it alters the probability of the proposition, but that does not mean that the original estimation was wrong because probability is always based on the available evidence. Later, he suggested five postulates that are necessary and sufficient conditions for validating scientific inferences. Jin Yuelin, a Chinese logician and philosopher who was influenced by Russell, shares similar views to Russell's but asserts stronger criticisms toward Hume's ontological and epistemological assumptions.

Frederick Will questions Hume's assertion that there is no evidence that the future will be like the past; hence, one cannot make inferences about the future. As a reply to this, Will discusses the meaning of the future. The future does not always remain as the future, but, as time passes it can become the present or the past. When this happens, we have the opportunity to learn more about the laws that have been stated previously. He explains this by saying that in 1936, 1937 and 1946 is the future, but in 1946, 1937 to 1946 ceases to be the future. However, this argument by Will has been criticized for not addressing the real problem of induction.

Induction in the Social Sciences

Émile Durkheim (1858–1917) pioneered the use of induction in the social sciences, particularly in the field of sociology. He emphasized the importance of explaining social phenomena on the basis of empirical evidence collected through objective observations, unlike other social theorists of his time who explained social phenomena through philosophical and metaphysical theories. He emphasized the importance of producing theories based on observations. In his view, a social phenomenon has to be observed in a similar manner as natural phenomena. Social phenomena can be explained in terms of social forces, which work on individuals just as do the forces that work on natural phenomena. He believed that preconceived ideas may distort the observation of a social phenomenon; therefore, he emphasized the importance of setting aside preconceived ideas. He, however, believed in defining the social phenomenon under investigation in advance to ensure the collection of the relevant facts to explain the social phenomenon scientifically. According to Durkheim, observations that are free of preconceived ideas on a clearly defined social phenomenon will enable true generalizations to be made regarding the phenomenon.

A *pure* form of induction is impossible in the social sciences because most researchers are guided by some theoretical ideas. It is also impossible to observe a social phenomenon objectively without some idea of which concepts are being observed or how each concept is defined. The choice of concepts and how these concepts are defined are necessarily based on some preconceived ideas or theoretical background. Owing to these problems, social scientists sometimes adopt a revised inductive methodology.

Most social studies that use inductive logic focus mostly on describing a social phenomenon in detail. Even though such detailed descriptions may be highly useful in explaining a phenomenon, induction is not often used directly to explain social phenomena. Even if generalizations are made through induction, these generalizations are always tentative and may be subject to revision because further research may reveal a different result.

In addition to this, social scientists often adopt different ontological and epistemological

assumptions than those used in the classical version of induction. The most important difference in the adaptation of induction in the social sciences is that social science investigation involves some preconceived ideas regarding how a social phenomenon is defined and what needs to be observed. These definitions are usually clearly stated to allow others to evaluate the conclusions and replicate the findings. Using a qualitative approach in the social sciences sometimes reduces the preconceptions and theoretical baggage used in social research, but such studies often use very different ontological assumptions than induction.

LOGIC AND LANGUAGE

The word *logic* originated from the ancient Greek word *logos*, which means “the word” or “what is spoken.” The exact meaning of the term *logic* is debatable among philosophers, but it is often understood as the study of arguments. As a discipline, it was studied in several ancient civilizations of the East and the West. The Greek philosopher Aristotle (384–322 B.C.E.) established it as a formal discipline in the West, while logic was developed independently in ancient India by Jains and Buddhists without any influence from Greece. Development of Indian logic dates back to the 6th century B.C.E. Indian logic is grounded in the Vedic theory of knowledge. Its initial concentration was on the freedom of soul from matter through systematic reasoning. Indian theories of inference cannot be easily distinguished into the deductive or inductive categories. The study of Indian logic is based on the Anviksiki school of logic by Medhatithi Gautama, as well as the Sanskrit grammar rules by the ancient Indian scholar Panini, which also influenced the famous Sanskrit epic the Mahabharata, among other works.

Aristotelian logic by far has found the widest application in philosophy and mathematics. Aristotle’s work is contained in six texts collectively named the *Organon* (“tool” in Greek), reflecting his approach to logic. Aristotle’s major work on logic includes *Categories*, *On Interpretation*, *Prior Analytics*, and *Posterior Analytics*, in which he discusses his system for reasoning and for developing sound arguments. His tradition was taken forward and developed by Islamic and medieval European logicians in the mid-14th century. The famous Arabic authors include al-Farabi, Avicenna, and Averroes.

Subsequently, the study of logic became less popular until it was revived in the mid-19th century.

This period witnessed the rapid development of mathematical, or symbolic, logic. Toward the end of the 19th century, three overlapping traditions in logic could be distinguished. The first, the *algebraic school*, focused on the relation between correct reasoning and mathematical operations. The *logician school* codified the underlying logic of scientific discourse into a single system. The *mathematical school* is the amalgam of the branches of mathematics such as geometry, arithmetic, and set theory. Mathematical logic has now come to be a central tool of contemporary analytic philosophy.

Aristotle’s Logic or Traditional Logic

Since Aristotle is widely regarded as the founder of logic, with profound implications for modern-day theorizing, aspects of his work relevant for the present discussion will be described here. Aristotle was the first to analyze *syllogisms*, which remained an important component of logic until the second half of the 19th century. A typical syllogism comprises an argument with three parts, namely a major premise, a minor premise, and a conclusion. The first two premises share exactly one term and entail the conclusion. This common term could appear as a subject in one and predicate in the other premise (*first figure*), subject in both premises (*third figure*) or predicate in both the premises (*second figure*). The conclusion contains the two nonshared terms of the premises. A particular combination of premises and conclusion is called a *mood*. Syllogistic logic is closely related to deductive reasoning as described below. In its original form, quantified conclusive statements were inferred from two quantified statements or premises. Basically the syllogistic language is confined to four sentence types:

Universal affirmative (A): All A are B

Example: All birds have wings

Particular affirmative (I): Some A are B

Example: Some birds are reptiles

Universal negative (E): No A are B

Example: No birds are animals

Particular negative (O): Some A are not B

Example: Some birds are not herbivores

Table I The Square of Opposition at a Glance

	<i>Affirmative</i>	<i>Negative</i>
Universal	A	E
Particular	I	O

This leaves conventional labels like A, I, E, O. These code letters are derived from the vowels of the two Latin words *affirmo* and *nego*. From here, A and O propositions and E and I propositions are contradictory. Propositions are contradictory when the truth of one implies the falsity of the other, and vice-versa. For example, where *All cats are mammals* is true, then *Some cats are not mammals* must be false. Propositions A and E are contrary where both of them together cannot be true. Propositions I and O are subcontrary where it is not possible for both to be false. If the statement *All days are long* is false, then *Some days are not long* must be true. Two propositions are said to be in *subalternation* when the truth of the first, the *superaltern*, implies the truth of the second, the *subaltern*, but not conversely. A proposition stand in the subalternation relation with the corresponding I propositions. The truth of the A proposition *All cars are four-wheelers* implies the truth of the proposition *Some cars are four-wheelers*. In traditional logic, the truth of an A proposition implies the truth of the corresponding I proposition and the truth of an E proposition implies the truth of the corresponding O proposition. Consequently, the falsity of an I or O proposition implies the falsity of the corresponding A or E proposition, respectively.

There is also another way to distinguish these propositions, and that is by arranging them in the *square of opposition* (Table I). The square is a diagrammatic representation of the previously described relations between these four propositions.

Some modifications have been proposed to the original square of opposition and other changes to Aristotelian syllogism, including an inductive approach that involves experimentation. A detailed description of these, however, is beyond the scope of this entry.

Logic in Contemporary Times

In the current era, logic is understood as the science of reasoning or reliable inference—whereby a

mathematician is interested in mathematical concepts and relations, or a philosopher is concerned with correct reasoning. Logical arguments rely on deductive or inductive reasoning. Under deductive reasoning, or top-down logic, valid conclusions are reached on the basis of given statements or premises, whereas in inductive reasoning, conclusions are reached by generalizing from an initial set of information or data base. For instance, if one determines or calculates that the probability of developing a flu increases if one lives in a cold environment, then it is reasonable to conclude that flu may be caused by cold. Thus, formulating explainable theories is important for induction. On the other hand, deductive reasoning takes place with the help of natural language; hence, a relation between natural and formal language assumes importance. Two examples of deductive reasoning:

Premise 1: If dolls are made out of chocolate,
then baby Anna is happy

Premise 2: Dolls are made out of chocolate

Conclusion: Baby Anna is happy

Premise 1: If the younger sister is sleeping, the
older sister is playing

Premise 2: The younger sister is sleeping

Conclusion: The older sister is playing

The premises given in both the examples are not facts about the real world, but the conclusions drawn are true as the premises are true. This is an essential property of reasoning in logic where the validity of conclusion is dependent upon the premises. Contrast this with the conclusion drawn below which is not valid in nature:

Premise 1: It is sunny or it is not raining

Premise 2: It is sunny

Conclusion: It is raining

The present entry lays stress on natural language and deals with a series of theories and supporting research studies that support the idea that human

reasoning and logic are well connected wherein meanings of linguistic expressions correspond to expressions of classical logic. The focus is on symbols of classical logic such as $\vee$, $\wedge$, $\neg$, $\forall$ that correspond to English words *or*, *and*, *not*, *all*, and on the complex interactions of $\&$, *or*, *not*, and quantificational expressions like *every*. These are called *logical connectives* or *logical operators* and work to join sentences in either natural or formal languages. The thrust is on how humans are biologically endowed with the capacity to reason logically, a capacity that could be studied through human languages consequently lessening the divide between the study of classical logic and philosophy of mind.

Alignment between this specific aspect of language and logic could be understood in terms of historical developments. The Chomskyan revolution in linguistics occurring during the 1980s, based on the work of Noam Chomsky, changed the equation between logic and natural language, helping to bridge the gap between natural and formal language. Structural linguists aimed at taxonomic study of languages before the revolution took hold. The mathematical logic of the structural era maintained a mind- and speaker-independent notion of language that did not advance the cognitive and psychological orientation toward language. Newer orientations with respect to language painted a more logical picture of human reasoning.

Language and Logic

Philosophy of language and logic share an important intimate relationship, as stated previously. Language is used to express thoughts and logic deals with concepts or objects of thought. Thus the study of language and logic has assumed great importance in modern-day study of mind.

The literature on cognitive science and linguistics is rife with debates on whether formal logic as studied by mathematicians plays a role in human reasoning or thinking. Classic experiments conducted in the structural era during the 1960s and 1970s presented adult participants with an array of cards. Participants were told beforehand that each card contained a letter on one side and a number on the other side. Furthermore, the cards which had a vowel on one side definitely contained an even number on the other side. The task

of the participants was to find out the cards that violated the given rules. Deductive logic dictates that the right selection for such a violation would be cards with a vowel and cards containing the odd number. The correct answer was given by only a handful of the participants. When these abstract rules and problems were replaced by a concrete problem and rule that gave contextual information in another experiment, the performance of the participants improved. The adult participants could perform better because they could make use of the contextual information. Conclusions consistent with beliefs or world knowledge are easier to draw than conclusions that rely on abstract content. Thus, many researchers believe that humans do not reason in a logical manner, paving a way for disconnect between logic and human reasoning.

Logical nativism, a result of the Chomskyan revolution, was offered as an alternative to the nonlogical picture of human reasoning. Logical nativism explains that humans are endowed with the innate faculty for logic. This view has gained momentum by research on human languages, favoring close alignment between formal and philosophical logic. Work carried out under this tradition shows that linguistic expressions like *and*, *or*, *every*, and *some* carry the same meaning as they carry in formal logic. Therefore, these linguistic expressions are called *logical expressions* and their semantic knowledge or truth conditions form part of *universal grammar* (UG) that is accessible to all irrespective of the individual language used or spoken.

Consider the truth conditions for logical disjunction ($\vee$) corresponding to the linguistic expression *or* that produces a value of true if at least one of its operands or propositions (A, B) is true or when both are true. The English word *or* receives the same interpretation as is true of disjunction in classical logic and hence is labeled inclusive *or*.

Contrast inclusive *or* with *exclusive-or*, which is false when both propositions (A, B) are true. The conjunction operator $\&$ corresponding to the linguistic expression *and* has a different set of truth conditions associated with it, according to which a statement is true only if both of the operands (A, B) are true. This is also called *logical conjunction* ($\wedge$). Table 2 details the values for conjunction:

Table 2 Truth Conditions for Logical Conjunction
($A \wedge B$)

Operands or Propositions		
A	B	Interpretation
True	True	True
True	False	False
False	True	False
False	False	False

Now, assuming that disjunction is inclusive-or in English, ($A \vee B$) is false when A and B are both false. However, the introduction of negation reverses truth-values, yielding one of de Morgan's laws of propositional logic where negated disjunctions generate a *conjunctive* entailment. Thus, $\neg (A \vee B)$, where $\neg$ is the symbol for negation (Table 4), could be rewritten as $(\neg A \ \& \ \neg B)$ or $(\neg A \wedge \neg B)$. This is how negated disjunctions work in the English language. Take a simple example in English like, *John did not speak Spanish or French* that could be understood as *John did not speak both the languages*.

A classic study looking at this phenomenon in English-speaking children had test sentences like *The girl who stayed up late will not get a dime or a jewel* versus *The girl who didn't go to sleep will get a dime or a jewel*. Only the former sentence represents $\neg (A \vee B)$; a look at Table 3 will help in understanding the associated truth conditions:

The results show that young children were able to grasp the idea in the statement representing $\neg (A \vee B)$ that was only evaluated as true when the girl did not receive a jewel and the girl did not receive a dime (highlighted in Table 3).

Evidence From Cross-Cultural Child and Adult Language Research

Arguments favoring disconnections between logic and human reasoning would show that sometimes adults would interpret negated disjunctions in a way that do not appeal to classical logic. For instance, speakers of languages like Japanese or Chinese would understand a statement containing negated disjunctions in a differential manner. For the example sentence, *John did not speak Spanish or French*, these speakers are more likely

Table 3 Truth Conditions Associated With $\neg (A \vee B)$

Operands or Propositions		
A	B	Interpretation
True	True	False
True	False	False
False	True	False
False	False	True

Table 4 Truth Conditions Associated With Logical $\neg$

A	$\neg A$
True	False
False	True

to interpret that *John either did not speak Spanish or he did not speak French*. This interpretation arises as the structural arrangement of negation and disjunction in Japanese and Chinese sentences, and is not comparable to English sentences. In Japanese and Chinese, disjunction is interpreted as taking scope over negation or the wide scope disjunction interpretation. This could be rewritten as $\neg A \vee \neg B$.

Even for adult speakers of English, ($A \vee B$) is subject to pragmatic or experience-based inferences implying that the disjunction of these two operands is understood as *not both*. As a result, adults would avoid using a statement like *John speaks Spanish or French* as a description of situation where *John speaks both the languages*. This is where adult reasoning does not conform to classical logic. Unlike adults, child speakers of English understand the English *or* as consistent with classical logic.

In order to show that disconnections between logic and human reasoning are only the result of experience or input, it is important to show that children irrespective of their native language community understand *or* in terms of classical logic. This is because all children have access to the linguistic principles of UG. Therefore, to begin with, young children across the world interpret *or* in a similar manner despite idiosyncratic language differences that may be absorbed later in the course of language acquisition consistent with the input from the environment. Children are expected to reason more logically than adults precisely owing to innate constraints in place.

Confirming evidence accrues from a developmental study conducted on 5-year-old Japanese-speaking children versus adults. In critical trials, both groups of participants judged whether a Japanese test sentence containing negated disjunctions would be true if one of the individual hypothetical situations corresponding to two operands (A, B) was true and the other was false. The judgments of Japanese adults and children differed where adults accepted the test sentence and children rejected it. Japanese children thus behaved like English-speaking children and adults. The proposed *semantic subset principle* explains this finding. The subset principle forces children to adopt the subset value of a parameter as their initial setting, and *inclusive-or* is one of them. The value is abandoned later only on the basis of positive evidence available in the local language. This makes sense because if children adopted the superset value, they would generate sentence meanings that are not licensed in the local language, in addition to ones that are licensed.

Details of Good Testing

To reiterate, logical expressions or words (e.g., *or*, *every*) are not only subject to inherent semantic knowledge, as has been shown in the case of children, but also subject to pragmatic influences. This gives rise to conversational implicatures wherein a hearer interprets that a speaker using a weaker term like *or* was not in a position to use a stronger term like *and*. An important aim for any testing exercise geared toward uncovering details of innate semantic principles is to build situations where these implicatures are canceled out. This section will focus on one such testing scenario. A context where these implicatures are canceled out is called the *prediction mode*. For instance, consider a sentence like *There will be a blue or red car in the showroom*. Adults would consider a statement like this to be true even if both types of car are found at the showroom after the sentence is uttered. This happens because some of the circumstances linked with the English word *and* are also linked with the English word *or* as noted previously.

The prediction mode introduces uncertainty about the outcome, a feature that could be fruitfully employed for making the testing conditions

felicitous. The felicitous condition is based on conversational implicatures where a speaker is justified in using the word *or* if he/she is unsure about what will happen in the future. This could be successfully employed for testing children for the purpose of uncovering innate semantic principles. Describing these testing procedures in detail deserves an important mention, as some of the work done could lead to the erroneous conclusion that children's reasoning does not conform to classical logic as has been shown before for adults, or in other words that for children English *or* corresponds to an *exclusive-or* reading. Such results are the fallout of experimental manipulations biased toward exclusivity. Consider situations where children were asked to pick either a red balloon or a blue balloon. Children under these testing conditions were actually found to pick the red or the blue balloon more often rather than choosing both colors together, implying that they cannot access conjunctive truth conditions associated with the English *or*, consistent with classical logic.

The previously described research thus suffers from two major drawbacks: first, that children were required to initiate a physical act which in itself has limited value when it comes to gauging the range or scope of truth conditions associated with the linguistic expression *or*; and second, these testing scenarios gave rise to conversational implicatures. The child may assume that if the adult tester wanted them to pick both types of balloon, she would have used *and* instead of *or*. Thus, it becomes critical to cancel these conversational implicatures in order to study the range of truth conditions associated with English *or* and accessed by children. Moreover, the very nature of the initiation of physical act shows that children only have access to one grammatical interpretation and these acts cannot be used to gauge whether children would show evidence for another interpretation in a different situation.

One such technique that takes into account all the good testing ingredients as mentioned earlier is called the *truth-value judgment task* (TVJT). In a typical version, two experimenters participate where one is responsible for presenting a short story with the help of toys and props and the other is responsible for manipulating a puppet that witnesses the whole story along with the child

who is being tested. At the end of the story, the puppet summarizes the events and presents a critical statement to be evaluated by the child. The child's task is to reward the puppet if the critical statement appears to be the best description of the story events and to punish the puppet if the critical statement is not an accurate description. The way the puppet is judged reveals whether the child has access to the range of truth conditions associated with English *or*. This can be achieved by manipulating experimental or story contexts, each associated with a particular truth condition. Children whose grammar lacks the inclusive-or interpretation should judge the presented critical statements as false in story contexts where both the operands (A, B) are true, whereas children whose grammar allows the inclusive-or reading should judge the same statement as true.

In a classical experiment conducted in the 1990s, children were shown to indicate knowledge of conjunctive truth-conditions associated with English *or* when conversational implicature of exclusivity was canceled out with the help of the prediction mode. English-speaking children were tested in the prediction and the description mode. In a description mode, the puppet simply described the events that had already taken place. Consider the previous example where a puppet might say, *There will be a blue or red car in the showroom* after, for example, the children had been shown a toy showroom containing both types of cars. Under such an example scenario, children in the prediction mode did much better than the children in the description mode.

Another testing scenario where the conversational implicature of exclusivity could be canceled is the use of the verb *can* in a sample statement like *Mary or Jane can finish the painting*. If this statement is understood as a generic one about the ability of either Mary or Jane to complete a painting, then the inclusive-or reading becomes available. Experimental manipulations like this in the past have also shown that children have access to the inclusive-or reading.

A glimpse of the following tables would make the differences clear where the crucial difference between inclusive-or (Table 5) and exclusive-or (Table 6) reading is highlighted in bold:

Table 5 Inclusive-or Reading as It Conforms to Classical Logic

<i>Operands or Propositions</i>		
<i>A</i>	<i>B</i>	<i>Interpretation</i>
True	True	True
True	False	True
False	True	True
False	False	False

Table 6 Exclusive-or Reading Also Arising From the Conversational Implicature of Exclusivity

<i>Operands or Propositions</i>		
<i>A</i>	<i>B</i>	<i>Interpretation</i>
True	True	False
True	False	True
False	True	True
False	False	False

An Explanatory Hypothesis: Modularity Matching Model

The Modularity Matching Model (MMM) described in this section serves as an organizing framework for explaining how and why a cognitive system (e.g., humans) would assign different reading to linguistic expressions when the expressions are subject to conversational implicatures. The MMM borrows theory from UG and within it the role ascribed to experience is minimal, at least in the acquisition of syntactic and semantic principles. The role of experience is limited only to setting parameter values as explained for the semantic subset principle. The model rests on two assumptions: first, that the operation of the language faculty is governed by specific principles which are not shared by other systems such as vision and memory. Second is the assumption of continuity wherein both the child and the adult language-processing systems are the same, or in other words the principles of the semantic or syntactic components are the same. According to the MMM, operations within the language faculty are organized hierarchically where the results of the analysis taking place at the lower levels are transferred upward for higher levels of analysis.

Operations taking place at the higher level components are called the *pruning principles*. These pruning principles apply to the output or structural descriptions of the lower level components. In cases where multiple outputs are transferred for higher levels of analysis, the pruning principles will maintain or reject these. Under such a scenario, pruning principles cannot influence the interpretations of already unambiguous sentences. For the current purposes, pragmatics or conversational implicatures can be understood as these pruning principles, while the analyses taking place at the semantic level would be lower in the hierarchy. In case of children who have yet to acquire the pragmatics, only one output from the semantic level dominates, which in this case would be the inclusive-or interpretation. The experimental manipulation described in TVJT was aimed at constraining the functioning of the higher level pragmatic components so as to understand the operations taking place at the lower semantic or syntactic levels.

Negation, Disjunction, and Quantificational Words

The study of logic and the study of formal semantics, or logical semantics, are closely tied. *Logical semantics* deals with the notion of entailments (also called *logical consequence*), which is a fundamental concept in logic. Entailment relations are relations between two statements and are considered true when one logically follows from the other within the framework of deductive reasoning. Consider the premises and conclusions explained previously, where conclusions are considered valid and logical if they follow from premises. Therefore, another exemplar from semantics deserves a mention. Moreover, this description will help to strengthen the arguments advanced in the previous section in favor of our innate faculties, with more focus on negation and disjunction as these interact with other phrases such as universally quantified noun phrases (NPs) (e.g., *every*) in the subject position of sentences.

To gauge how the interpretation of *every*, another logical expression, changes when it occurs in the object versus subject position, consider the following sentences: *Every researcher didn't write the paper* versus *The researchers didn't write every paper*. The interpretation of the first sentence is

ambiguous. On one glance, it could be understood to mean that every researcher did not write the paper or none of them did. This is the isomorphic reading, where the overt positions of negation and quantified NPs are aligned with their interpretation. Or in other words *every* is interpreted outside the scope of negation (*every* > *not*). On the other hand, it could be understood as some or at least one researcher writing the paper. This is the nonisomorphic reading, where *every* is interpreted inside the scope of negation (*not* > *every*). However, the interpretation of the second sentence is not ambiguous. Here, *every* is always interpreted within the scope of negation. This sentence could only mean that all the researchers did not write all the papers. Therefore, the interpretations of the interactions between negation and universally quantified NPs vary, depending upon whether *every* occupies the subject or the object position.

Other interactions have been noted between disjunction and the universal quantifier (Table 7). A sentence like *Every linguist who studies English or Hindi got the award* could be interpreted to mean that every linguist who studies English got the award and every linguist who studies Hindi got the award. Here, disjunction appears in the subject phrase of the universal quantifier. Similar interpretation for interactions between *every* and disjunction have been noted for languages like Chinese and Japanese. Compare this sentence with a sentence like *Every linguist who got the award studies English or Hindi* which could only be interpreted to mean either every linguist who got the award studies English or every linguist who got the award studies Hindi, but not both. Children from an early age are shown to differentiate between the sentences where the arrangement of disjunction and *every* gives rise to differing interpretations, thus yielding another linguistic principle where disjunction gives rise to a conjunctive interpretation when it occurs only in the

Table 7 Interactions of *Every* With Or

Statements	Interpretations
Every SUBJ [.....Or.....] PRED [.....]	Conjunctive
Every SUBJ [.....] PRED [..... Or.....]	Disjunctive

subject phrase of the universal quantifier. However, disjunction will give rise to a disjunctive interpretation when it occurs only in the object phrase of the universal quantifier. The following table underscores this difference:

It is important to point out that the conjunctive-versus-disjunctive interpretations arise as English *or* is inclusive in nature, corresponding to the interpretation it receives in classical logic. Thus, De Morgan's laws (after the 19th-century British mathematician Augustus De Morgan) are preserved not only at the level of logic but also for semantic interpretation in human languages.

Evidence From Cross-Cultural Child and Adult Language Research

Studies conducted on preschool children using TVJT show that their interpretation is not aligned with those of the adults in case of sentences when it comes to interactions of *every* in the subject position with that of negation. The way these sentences are structured can lead to ambiguities while interpreting quantificational expressions, because processing can occur at two different levels, namely syntax and semantics, as explained above for the MMM. Semantics is higher up in the hierarchy than syntax. Consider a phrase like *Everyone didn't read* could be interpreted as either *no-one read* $\forall x$ [person (x) $\rightarrow$ $\neg$ read (x)] or perhaps as that *some people did not read* $\neg \forall x$ [person (x) $\rightarrow$ read (x)]. In the former interpretation, based on syntactic level, the universal quantifier *every* takes scope over negation (*didn't*) while in the latter, negation takes scope over *every*. Therefore, processing taking place at these two levels may not be isomorphic in nature. Adults usually get the latter reading while children aged 4 years usually get the former.

Sentences like these were tested in a well-known experiment where the testing context involved three horses jumping over a fence. Two horses could successfully jump over the fence but the third horse could not. Toward the end, the puppet summarized and said *Every horse didn't jump over the fence*. The statement is true on the adult reading but false on the understanding that children usually show. But this asymmetric result gives rise to an important question on how

children eventually develop an adult level understanding. This question assumes importance in the light of a caveat where the semantic knowledge or truth conditions of the *none* reading satisfies or entails the truth conditions of the *not all*, or adult reading. Or in other words, if it is true that none of the horses jumped over the fence, then it also true that not all of them did, but not the other way round. Careful experimentation revealed that adults could be made sensitive to the *none* reading by suitable testing contexts.

Coming back to the same question of how children eventually converge on an adult-level understanding, they only need to add to their grammatical repertoire based on the linguistic input they receive from adults again implying compatibility with the innate principles of UG. Therefore, it makes sense to start with the dispreferred interpretation consistent with the already explained semantic subset principle. This line of reasoning is grounded on support from cross-linguistic literature such as the Chinese, where sentences like *Every horse didn't jump over the fence* are not ambiguous. Sentences like these only give rise to an isomorphic reading in Chinese. Adult Chinese speakers come up with the same interpretation as English-speaking children. Thus, assigning an English-speaking adult-like interpretation seems to be another case of parametric variation, where all children would seem to start with a subset value or an isomorphic reading corresponding to Chinese adult-like understanding. Starting with a superset value poses a learnability problem whereby children may never come across evidence or negative evidence that will be helpful in setting a native-like parameter value.

Atypical Population

In order to provide stronger support for the hypothesis of logical nativism, interpretations aligned with the syntactic and semantic levels in the MMM should accrue from developmental disorders (like autism) where linguistic knowledge has been argued to be developing atypically as compared to typically developing children. Autism is a part of a spectrum that is labeled as the autism spectrum disorder. It is a lifelong developmental disorder markedly characterized by difficulties with language and communication. A very recent

study was conducted on participants diagnosed with autism with a mean of 16 years and 3 months on *Every . . . not* sentences. The results show that the performance of these participants was very similar to a 4-year-old control group of typically developing children. The results hint at the possibility that even at an older age, participants with autism are unable to interpret these sentences in an adult-like manner, implying that the basic syntactic and semantic principles are intact. What seems to be disturbed is the acquisition of pruning principles, which comes later in development.

Final Remarks

A disconnect between logic and human reasoning seems to be a result of the way research was conducted on human logic in the past. Classical experiments reported in the 1960s and 1970s showed that human reasoning does not conform to the laws of logic. This has since been challenged with the help of work and developments taking place within the nativist approach to (or the Chomskian view of) language. With this approach, language acquisition is explained as a biologically driven process where learning occurs as a by-product of task-specific computational mechanisms. To reiterate, children are biologically endowed with core principles (common to all human language) of UG that are not dependent upon learning experience, as shown with the help of work on logical operators (*every*, *or*, *not*). The crux of UG dictates how human languages differ from each other. These variations are called *parameters*. As a result of this set-up, learning of language proceeds rapidly and effortlessly. The studies reported here provide evidence for a connection between logic and human thinking whereby human reasoning confirms to the laws of logic. Language is seen as an important window to this connection, favoring close alignment between formal and philosophical logic gauged through its study in children and adults with a focus on syntactic and semantic components.

LOGICAL THEORY

The word *logic* is generally used in two different ways. We use it to say such things as “Her logic seems faulty to me,” or “I disagree with his logic.” In these instances, we are using the word *logic* to refer to a person’s reasoning skills. However, the word *logic* can also refer to an academic subject that is defined as *the systematic study of the standards of good reasoning*. Humans have been thinking logically since prehistoric times, but the academic theory dates back to around the 5th century B.C.E. in Athens, where ancient Greek philosopher Aristotle taught logic classes and wrote treatises on logical theory. The new academic subject *logic* was not focused on reasoning about particular topics but was rather an examination of the standards any kind of reasoning must follow if it is to be considered *good reasoning*. This entry traces the origin and development of logic from ancient Greece through to the present day, including an account of arguments, the varieties of logic, the principles of truth and validity, and the contributions of major thinkers over the century.

At Aristotle’s time, the academic subject we now know as logic did not have this name, and it was only decades after his death that the term *logos* was used, attributed to a group of philosophers known as the *Stoics*.

The Birth of Logic

Throughout history, cultures have embraced intricate systems of reasoning with logical methods evident throughout all human thought. However, an explicit analysis of the principles of reasoning was only developed in three traditions, those of China, India, and Greece. Of these, only the logic descending from the Greek tradition, and in particular Aristotelian logic, has found wide application in mathematics and science. In ancient Greece, logic was known as *dialectic* or *analytic*.

Aristotle’s logic was developed further by Islamic and medieval European logicians and reached a high point in the middle of the 14th century. It was then several centuries later that logic became reinvented into an exact method of proof in mathematics. The development of modern-day *symbolic* or *mathematical* logic is one of

the most significant in its 2000-year history and arguably one of the most important events in intellectual history. Progress in mathematical logic in the first part of the 20th century, particularly in the works of Kurt Gödel and Alfred Tarski, had an impact on analytical philosophy and philosophical logic. Subjects such as modal, temporal, deontic, and relevance logic came into being.

Aristotle was born in Macedonia, to the east of the Greek peninsula. He was later sent to Athens to study at the academy of the famous philosopher Plato. The Greeks took the name philosophy from *philo*, to love, and *sophia*, wisdom: that is, the love of wisdom. The Greeks had already started questioning the myths and traditional explanations of the universe in written works and in recorded discussions, and they pioneered a radical new way to make sense of the world. They rejected myths and the pronouncements of authority on the basis that there was no *good reason* to accept their claims as true; that is, in correspondence with reality. In place of mythical stories and pronouncements, they looked for explanations that were based on unaided reason and on observation, both of which could be made by anyone. They set down their theories along with supporting evidence for their theories in writing and passed it around, so others could comment, discuss, and debate their findings. Theories were proposed and criticized, defended or revised, and rejected on the basis of reasoning and the available observable evidence—and without reference to myth or questionable statements of authority.

Thus, the first philosophers looked for rational explanations of the world and of the things within it. These accounts had to be justified based on reasoning and evidence alone. Ancient Greece was the birthplace of the philosophical tradition and created an intellectual revolution. Aristotle decided to make it his job to create a separate discipline that would study the universal standards of reason itself rather than reasoning about this or that particular theory. His theory of pure reason would help to sort out the complications for finding reasons for and against each and every theory. He went on to write many treatises on logical theory, known collectively as the *organon*, and much of it is as valid today as it was over 2,000 years ago. Academics still devote their lives to studying Aristotle’s works on logic, and new books are still appearing year after year.

The Basics of Logical Theory

Logical theory begins with the concept of an argument. An argument does not in this case involve any form of heated emotional dispute. When used in logic, it means *reasoning put into words*. For logicians, when you put reasoning into words, an argument is the result. When it comes to defining logical theory, a more detailed exposition is usually required. This generally involves the statement that an argument consists of one or more statements, termed premises, offered as a reason to believe that a further statement, termed the conclusion, is true—that is, it corresponds to reality. In logic, the word argument means *one or more premises offered as reasons or as evidence for the truth of a conclusion*.

When we are listening to an argument, it can be difficult to ascertain which statements are the premises and which are the conclusion. For this reason, the English language contains what logicians term *argument indicator words*. In order to let the audience understand when to expect the conclusion, the statement should be introduced using a word or phrase such as *in conclusion*, *therefore*, *thus*, *consequently*, and so on. *Premise indicator words* and *conclusion indicator words* enable a reader to follow the progression of reasoning.

Deductive and Inductive Arguments

Following in Aristotle's footsteps, logical arguments are divided into two main types: deductive and inductive. A *deductive argument* sets out to show that its conclusion must necessarily be true. That is to say, a deductive argument seeks to establish its conclusion conclusively. The implicit or explicit claim in a deductive argument is that if the premises are true, then the conclusion must absolutely be true too.

An *inductive argument* is an argument that seeks to show that its conclusion is probably true, although not necessarily. An inductive argument claims that only if the premises are true, the conclusion is likely or reasonably certain to be true.

Deductive arguments are made explicit by introducing the conclusion with words such as "therefore it must be true" or "it necessarily follows that" or "it is conclusively proven that" or

"therefore it is certain that" These types of phrases are known as *deductive indicators*.

An inductive argument is made explicit by introducing the conclusion with phrases such as "therefore it is likely that," "therefore it is probable that," or "therefore there it is reasonable to suppose that" These types of phrases are known as *inductive indicators*.

Valid and Invalid Deductive Arguments

When a deductive argument is successful in illustrating that its conclusion is true, if all its premises are true, it is termed a *valid* deductive argument. Deductive arguments that fail to show that the conclusions are true if their premises are true are termed *invalid* deductive arguments. Thus, a valid argument may be defined as a deductive argument, where it is the case that if the premises are true, then the conclusion must be true. An invalid argument may be defined as a deductive argument, whereby it is not the case that if the premises are true, then the conclusion must be true.

The following arguments are deductive since each aims to show that its conclusion must be true if the premises are true. Only the first argument is valid, however, with the second invalid. The arguments are deductive because each aims to show that all human beings are mammals:

1. All mammals have warm blood.
2. Therefore, it must be the case that all human beings have warm blood.
1. All human beings are mammals.
2. All cats are mammals.
3. Therefore, it must be the case that all human beings are cats.

This illustrates that not all reasoning is equal and that some reasoning is better than others. Validity is something that often puzzles us, since an argument can be valid even though it has false premises and a false conclusion.

Look at the following deductive argument:

1. All teenagers are millionaires.
2. All millionaires are Christians.
3. Therefore, all teenagers are Christians.

Even though the premises are false as well as the conclusion, the argument is a valid one. It is valid because if the premises were true, then the conclusion would have to be true too. The argument then fits the definition of what it is to be a valid argument. The premises are false, yet the argument is absolutely valid, which does not fit in with our common sense. This shows that in logic, true premises are not required for validity, and that the term *valid* does not equal true. An argument is valid just so long as it is the case that if the premises were true, then the conclusion would also be true. True premises are not necessary.

However, we naturally want more than validity from a deductive argument, we want the truth. When an argument is valid, and its premises are all true too, then the argument is termed a *sound* argument. A sound argument features two characteristics:

1. All of the premises are true.
2. It is a valid argument.

Since truth corresponds with reality, it is the ultimate goal of good reasoning. Thus, it follows that soundness, rather than simply validity, is the ultimate goal of a deductive argument. For reasoning to be worthwhile the deductive argument has to be sound as well as valid. Consider the following argument that is both valid and sound:

1. All whales are mammals.
2. All mammals are animals.
3. Therefore, it must be the case that all whales are animals.

The argument that was previously considered, involving teenagers and Christians, was a valid argument but it was unsound.

Strong, Weak, and Cogent Inductive Arguments

Inductive arguments that succeed in showing that their conclusions are probably but not certainly true, if the premises are true, are termed a *strong inductive argument*. Inductive arguments that fail to show that the conclusion is probably but not certainly true, if the premises are true, is termed a *weak inductive argument*.

So, it follows that a strong argument may be defined as an inductive argument, whereby it is

the case that if the premises are true, then the conclusion is probably true. A weak argument may be defined as an inductive argument, whereby it is not the case that if the premises are true, then the conclusion is probably true.

The following arguments are inductive, since each attempts to show that its conclusion is probably but not certainly true. The first is strong and the second is weak:

1. In all recorded history, it has never snowed more than 6 inches in Michigan in July.
2. Therefore, it will probably not snow more than 6 inches in Michigan in July.

1. Jan is a member of the Republican Party.
2. Some known communists have been members of the Republican Party.
3. Therefore, Jan is probably a communist.

This again goes to show that not all reasoning is equal and that some arguments are superior to others. An inductive argument may be strong even though it has false premises and a false conclusion. For example:

1. For the past 5 months, it has been snowing in Michigan every day. It is below 40° in Michigan, and the sky in Michigan is packed with snow clouds.
2. Therefore, it will probably snow today in Michigan.

While the premises are obviously false, as is the conclusion, the argument is a strong one. It is strong because if the premises were true, then the conclusion would probably be true as well: If the premise is true, then the conclusion is likely to be albeit not certainly true, so the argument fits with the definition of a strong argument.

As before, however, strength is not sufficient for an inductive argument; we also require truth. If an argument is strong and its premises are true, then the argument is termed a *cogent argument*. A cogent argument has two properties:

1. All the premises are true.
2. It is strong.

Truth is the ultimate goal of reasoning, and cogency is the ultimate goal of inductive arguments.

The following argument is simultaneously strong and cogent:

1. Most cars run on gasoline.
2. The president's limousine is a car.
3. Therefore, the president's limousine probably runs on gasoline.

The previous example that involved Michigan and snow was strong, but it was not cogent.

Consistency, Implication, and Equivalence

Using reason, we have judged deductive arguments as either valid or invalid and assessed the strength of inductive arguments. We also need to use reason to help us decide whether or not two of our beliefs are logically inconsistent or in conflict, and reason will also help in identifying logical relations between beliefs. It is because of this that logical theory also seeks to examine the logical relationships that exist between *declarative* statements and statements' logical properties. There are four terms of special importance: *consistency*, *inconsistency*, *implication*, and *equivalence*.

Consistency and Inconsistency

Two statements are consistent if (and only if) it is possible both are true. Two statements are inconsistent if (and only if) it is not possible both are true. For example, the following statements, given their standard meanings, are consistent:

1. Anna is 11 years old.
2. Anna is a violin player.

And the following statements, given their standard meanings, are inconsistent:

1. Anna is 11 years old.
2. Anna is a teenager.

Implication

One statement implies a second statement if (and only if) it is not possible that the first statement is true and the second is false. Put another way, a statement S implies a statement P when, and only when, it is the case that if S is true, then

P is true. For example, in the following case, the first sentence implies the second:

1. Elizabeth is 14 years old.
2. Elizabeth is older than 10.

However, in this next case, the first sentence does not imply the second:

1. Elizabeth is a netball player.
2. Elizabeth is a millionaire.

Equivalence

Two statements, S and P, are equivalent if (and only if) S implies P and P implies S. Put another way, the two statements are equivalent when and only when it is not possible that they differ in terms of truth and falsity: If one statement is true, then the other is true. If one statement is false, then the other is false. In the following example, the two statements are logically equivalent:

1. Elizabeth is taller than Anna.
2. Anna is shorter than Elizabeth.

These two statements on the other hand are not equivalent:

1. Elizabeth is older than Anna.
2. Anna is 11 years old.

Necessity and Contingency

Our reason comes into play too when we decide if a statement is necessary or contingent, and logic is involved in defining the relevant terminology to ensure our thinking is as clear as possible here. There are four important terms to consider: *a necessary truth*, *a necessary falsehood*, *a contingent truth*, and *a contingent falsehood*. These are defined as follows:

A statement is necessarily true if it is in fact true and cannot possibly be false. That is, that the statement is true in all possible instances, and that there are no circumstances whereby it could be false. For the purpose of logical theory, *possible circumstances* can be defined as a circumstances whose descriptions are nonself-contradictory. This is the most encompassing concept of possibility conceivable to humankind.

A statement is necessarily false if it is false and there is no possibility of it being true. That is, that the statement is false in all conceivable circumstances and there are no possible situations in which it would be true.

For example, the following statements are all necessarily true, given their standard meanings:

1. All squares have four sides.
2. The derivative of a constant is zero.
3. Number 4 is greater than number 3.

According to their standard meanings, the following statements are of necessity false:

1. All squares have five sides.
2. $1 + 1 = 3$.
3. Number 5 is less than number 3.

Contingency

A statement is contingently true if it is true but there are possible circumstances in which it would be false. That is, it is true but may have been false should circumstances have been sufficiently different.

A statement is contingently false if it is false but there are possible circumstances in which it would be true. That is, it is false but may have been true if circumstances had been sufficiently different.

Contingent truths could be illustrated thus:

1. The Mamas and the Papas performed at Woodstock in 1969.
2. It is sunny in Detroit on September 22, 2010.

Examples of contingently false statements could be:

1. Bob Dylan played Woodstock in 1969.
2. Richard Nixon became president in 1960.

The Five Branches of Logic

Now that we have defined the main concepts of logic, we can take a look at the five important branches of logical theory. These are *categorical logic*, *predicate logic*, *truth-functional logic*, *modal logic*, and *informal logic*.

Categorical Logic

Categorical logic is concerned with finding the universal standards governing categorical arguments. Categorical arguments look like this:

1. All dogs are mammals.
2. All mammals have lungs.
3. Therefore, all dogs have lungs.

Aristotle was the first to discover and treat systematically universal standards of logical reasoning. He began by deconstructing categorical reasoning into essential elements and then studied how to fit the parts together to make the different forms taken by categorical reasoning. By making precise definitions for the types of sentences that make up categorical arguments and defining a categorical argument (syllogism) precisely, he discovered that there are four basic forms a categorical sentence can take. From this, he deduced that there are 256 basic forms of categorical reasoning, 24 of which are unconditionally valid reasoning patterns.

Aristotle devised from this basis a set of general algorithms capable of determining precisely in every possible case whether a syllogism is valid or invalid. (An algorithm is a precise rule for completing a task that guarantees a definite outcome, after the accomplishment of a finite series of steps.) Aristotle also developed a precise axiom system, which allowed him to prove, in a mathematically precise way, the validity or invalidity or every possible form of categorical reasoning.

In brief, a categorical argument is made up of categorical statements. Categorical statements express the relationships between two categories (groups of things) by stating that either all, none, or some of one category belong, or do not belong, to a second category. A sentence making up a categorical argument can have four forms. Supposing A and B stand for categories (of things), then we can say:

1. All A are B.
2. No A is B.
3. Some A are B.
4. Some A are not B.

This can be expressed as:

1. All dogs are mammals.
2. No dogs are reptiles.
3. Some dogs are pets.
4. Some dogs are not pets.

Every categorical sentence can be divided into four parts: quantifier, subject term, predicate term, and a copula. The subject term identifies the subject category or what the sentence is about, the predicate term is the identifier of the predicate category, while the quantifier states how many subject category members (of dogs) belong to or do not belong to the predicate category (of mammals). The copula (*are*) links subject and predicate and indicates whether the quantity refers to things belonging to the predicate category or those that do not belong to the predicate category.

Truth-Functional Logic

In truth-functional logic, arguments look like this:

1. If it is daytime, then the sun is out.
2. It is daytime.
3. Therefore, the sun is out.

This type of argument dates back to the Stoics of the 3rd century B.C.E. The logic was updated by the philosopher and mathematician Gottlob Frege in the latter part of the 19th century. Truth-functional logic concerns itself with declarative sentences that are compound if they contain one or more sentences within them or simple if they don't. A sentence operator is a word or phrase that links one or more sentences into a compound sentence. For example:

Plato taught at the Academy, and Aristotle taught at the Lyceum.

In this compound sentence, *and* is the operator joining the two simpler sentences together. A sentence has the truth-value of true if it expresses a true proposition, and a truth-value of false if it expresses a false proposition.

Predicate Logic

Predicate logic was invented by Gottlob Frege, who tried to construct an axiomatic proof originating with statements of pure logical theory. After following a set of deductively valid inferences, the proof would lead to the principles of pure arithmetic or number theory, which would eventually reach out to all mathematical principles. Frege's theory sought to bring new domains under the mantle of logic through generalization, a form of logic that is also called *modern-day* logic or *symbolic* logic." It is called this because it is a logic expressed in symbols and formulae that resemble those of mathematics, taking it beyond the scope of traditional logic. Frege invented the first *formal* language for logic theory, giving it a complete system of syntaxes and semantics, thereby giving logic a new expressiveness and power.

Modal Logic

Modal logic studies the modes of truths and how they relate to reasoning. Modes of truth are the various ways that a proposition can be true or false. These include necessary truths, necessary falsities, contingent truths, and contingent falsities. There are also possible truths and falsities.

In logic, a circumstance is *possible*, so long as its description is not self-contradictory. In this way, *possible* is not the same as *probable*. Some circumstances are possible although unlikely; for example, a person winning a million dollars in the state lottery 3 days in a row is a possible outcome but not a probable one. However, some things are not even possible because their descriptions are self-contradictory; for example, there is a woman who is taller than herself.

Aristotle founded modal logic, but the first modern system is ascribed to Clarence Irving Lewis, usually cited as C. I. Lewis. Today, work in modal logic rests on one or another version of *possible world semantics*. The notion of a possible world, of a way things might have or could have been, can be used to express the whole of logical theory and resolve theoretical problems that would otherwise remain unresolved. Modal logic is of interest to philosophers because many

of the interesting arguments in the history of philosophy—those about existence, the soul, free will, God, and so on are modal in nature. *The Nature of Necessity*, published in 1974, was one of the most important works in the history of modal logic. Alvin Plantinga presented a new version of Anselm of Canterbury's (1033–1109 C.E.) famous ontological argument for the existence of God by using modal logic, establishing Anselm's argument as valid, and defending it against objections.

Informal Logic

Whereas formal logic applies to areas of study that consider reasoning as abstract from other areas, informal logic is concerned with the informal aspects of logical theory. There are three important branches of informal logic: the study of definitions, the study of informal fallacies, and the study of inductive reasoning.

Definitions are explanations of the meanings of words or phrases. If we do not define words properly, our reasoning may become sidetracked, so the art of definition is an important element in logical theory.

A *fallacy* is an error in reasoning. The ability to recognize a fallacy is considered an important logical skill. Fallacies should not be persuasive, but they often are. They can be created unintentionally or intentionally to deceive people. Most fallacies involve arguments, whereas others can be involved in explanations, definitions, or other forms of reasoning. The term *fallacy* can be used more broadly to highlight false beliefs or causes of false beliefs. An informal fallacy is fallacious due to both its form and content, whereas formal fallacies are fallacious because of their logical form.

Aristotle was again the first person known to consider fallacies, and he produced a list of common informal fallacies—there are now a huge number catalogued.

Inductive reasoning is used in everyday life, in science and in the law as well as in numerous other contexts. There are 12 basic types of inductive reasoning, and understanding them can give us an insight into an extremely useful logical skill. During the 19th century, the English philosopher John Stuart Mill formulated the rules of induction

that remain in use today. Scientists run tests in laboratories aimed at getting to the causes of things, and health departments use the principles laid down by Mill, known as *Mill's rules* when the researchers are attempting to track down the sources of disease.

Other Types of Logic

Paraconsistent logic is a branch of logic which is nonexplosive, whereby a contradiction does not imply the truth of each and every sentence. Its rules of inference are such that not every statement follows from a contradiction. Paraconsistent logic gives up the classical *principle of explosion*, arguing that it should be possible to reason in a logical discerning way beginning with a contradictory theory and not ending in meaningless triviality.

Dialetheism claims that some contradictions, at least, are true. This nonformal system of logic states that were one to exist, this would be a *true contradiction*. For at least one sentence *S*, both *S* and $\neg S$ are true at the same time, rejecting the *law of contradiction* principle; in other words, rejecting the principle that lays the foundation for the entire realm of classical logic.

The Value of Logic

The principles of logic are not just an academic exercise; they are practical guides that can be used to correct reasoning. Just as the principles of accountancy ensure we keep a correct set of books and the principles of arithmetic aid us in adding, subtracting, multiplying, and dividing correctly, the principles of physics enable us to plan landings on the moon, the rules of photography help us to take better pictures, and so on. Not all of us reason correctly all the time; we tend to make logical errors at least occasionally. In paying attention to the principles of logic, we have the tools to work things out when matters get complicated.

MATHEMATICS, ANTIQUITY

The period of antiquity usually refers to the time the first records of human civilization were recorded up to the collapse of the Western Roman Empire. In reality, this temporal reference point is arbitrary because mathematical activities did not exist only in this part of the world. The adoption of this time framework was influenced by the state of mathematical practices today, which is profoundly Greek axiomatic-deductive in structure, and by the Western points of view of historians of mathematics. However, mathematics has always been, and still is, a social activity that societies have practiced—one which is linked to their ways and cultures. Historically, it emerged in different ways. Mathematizing was brought about by practical necessities such as agriculture, architecture, and the scientific activities of those times. In many instances, these practical techniques led to more theoretical inquiries such as those exploring the nature of shapes and measurement.

Through the study of the history of mathematics, it can be seen that this body of knowledge was transmitted and transformed, rediscovered and synthesized in different kingdoms, states, epochs, and cultures. The study of mathematics in antiquity is the study of the interweaved nature of this most basic human activity.

Mathematics cannot be detached from its context. It is important to understand that these activities were part of societies and cultures, each

with their own traditions, beliefs, and needs. Therefore, it is natural that mathematics developed differently in different parts of the world. In interpreting history, it is important to define which activities could be categorized as mathematics. For practicality, many of today's historians have simply considered activities that appeared similar to our modern mathematics, like counting, arithmetic, measurement, and geometry. In the past, however, mathematics was more intertwined with religion, science, commerce, governance, engineering, and architectural pursuits. This is very different from the current state of mathematics, which despite being still highly influential to these same fields, is regarded as its own separate area of intellectual inquiry.

The Importance of Historical Artifacts

The most important factor that drives our knowledge about mathematics in antiquity is the availability of artifacts. Our knowledge of the ancient world is limited because only a few documents have survived. The consequence is that the mathematical histories of societies with fewer archaeological materials might appear to have engaged less in mathematical activities. In addition, societies that were relatively small would have fewer artifacts likely to have been preserved. This is why in the study of ancient mathematics, the focus is usually on the Egyptians, the Mesopotamians, the Chinese, and the Greeks. Larger societies produced more mathematical materials that lasted

much longer; yet even among those societies, modern understanding varies because of geography and the ways they recorded their mathematical activities. For example, Mesopotamians used clay, a more durable material than the papyri used by Egyptians, which disintegrated easily. This is why more is known about Mesopotamian mathematics than Egyptian. For Chinese mathematics, records from this time were almost surely written for the central government, which could have resulted in a skewed view of the purposes of mathematics. Documents written by Chinese mathematics practitioners who were not in civil service are rare. Finally, Greek mathematics was preserved through documents copied by the medieval Persians and Arabs, who translated and transformed them, later transmitting them back to Europe. Without these documents, significantly less would have been known. It is therefore important to remember that our understanding can never be complete because we are basing our findings only on limited archeological artifacts.

Practical and Theoretical Mathematics

Current historians of mathematics recognize that interpretations could be misguided by presentism. The most fundamental aspect of mathematical practice today is the concept of proofs, generalized for all possible situations, using an axiomatic-deductive style. A proof starts with axioms, or assumptions that are considered true, and then is followed by an unbroken sequence of argumentation that arrives at a conclusion, the statement that needs to be proven. This replicates the style found in Euclid of Alexandria's textbook *The Elements*. This ancient Greek way of mathematics is the mold that modern mathematicians aspire to follow. Exactness is a necessity and approximations are not valid. Many mathematical problems are not directly integrated with practical activities and many are not even concerned with things that are tangible. Mathematical text is conceptually dense. It assumes the reader knows the previously proven theorems necessary to understand the text. These are characteristics of the practices of small groups of mathematicians from the later period of ancient Greek society before it became part of the Roman Empire. The leaning toward the more *theoretical* or not directly useful as opposed to

practical mathematics is what modern mathematicians have adopted and was the practice copied from this group of ancient practitioners. Nevertheless, the majority did not share this type of intellectual endeavor. This style of mathematics was not the only prevailing practice, nor was it the most common in this period.

Categorization by Geography

In the ancient world, mathematical ideas were exchanged across societal borders. The lifetimes of civilizations overlapped and influenced each other's mathematical progress. Despite this, historians usually adopt a geographical demarcation rather than a temporal framework for their analyses. Consequently, the history of ancient mathematics is not subdivided such that mathematical activities for a certain century include all societies creating mathematics at that time. As noted earlier, this is because of the limited archeological artifacts and knowledge available. For practicality, historians usually use geographical divisions including Egyptian, Mesopotamian, Chinese, and Greek mathematics.

Egyptian

The history of ancient Egypt is typically divided into three phases: the Old Kingdom (1550–1069 B.C.E.), the Middle Kingdom (2055–1650 B.C.E.), and the New Kingdom (1550–1069 B.C.E.) when only one king ruled the land. Culture thrived and expanded during these periods because of political stability. After these kingdoms, Egypt was conquered by Alexander the Great and ruled throughout the Hellenistic period (305–30 B.C.E.) by various Ptolemaic dynasties (Macedonian Greek royal families) until it eventually became a province of the Roman Empire.

Current knowledge of Egyptian mathematics is limited because artifacts available for study are scarce. Only a few have been found containing mathematical text including the Rhind, Kahun, and Berlin papyri, the Akhmim wooden tablets, a leather roll, and the Moscow papyrus. All of them date to the Middle Kingdom. The reason for the rarity of artifacts is because excavations are limited to uninhabited areas close to the Nile valley, desert areas where papyri would have a greater chance of survival. Papyri would have less chance

of being preserved in the more humid inhabited areas adjacent to the river Nile. This circumstance makes it impossible to assess the extent of Egyptian mathematical activity at that time.

A fully developed decimal system of numeration already existed even before Egypt was unified under one ruler. In terms of writing, *hieroglyphs*, meaning sacred engraved text, were used for inscriptions on stone monuments, while a cursive form of writing called *hieratic* was used on papyrus for everyday purposes. *Demotic* is a later and more cursive version of hieratic. Only hieratic and demotic were used for mathematical text. The motivation for doing mathematics was practical; for instance, various technological pursuits. Discoveries of school texts used to train scribes describe problems in measuring areas of land, calculating agricultural production, and calculating the slopes of pyramids. Units of measurement were based on body parts. For example, a cubit corresponds to the forearm, which is 7 *palms* long, a unit that in turn is equivalent to 4 *fingers*. To perform fast calculations, Egyptians practiced multiplication and division through successive doubling or halving, working with powers of 10, using even numbers, and powers of two and their reciprocals. They used a system of fractions that is different from modern practices but made the magnitude immediately apparent: for example, expressing $5/19$ as $(1/6, 1/12, 1/114, 1/228)$. They also used precalculated tables to aid in division problems.

Important mathematical activities were used for various engineering projects such as stone mining. The calculation of stone volumes was essential to determine how many men could carry the weight and how long the work would take. These activities required people to have a simple way of calculation, a type of mathematics that can be understood by everyone involved. The Rhind papyrus contains a problem regarding the calculation of *seked*, a concept equivalent to the modern-day concept of slope. Mathematics was also important for agriculture, especially measuring land under cultivation. Every year, the Nile would flood the plains and the level of the flood would indicate the agricultural output for the next year. Therefore, it was important to measure and record these levels. In addition, the boundaries of agricultural lands that were previously flooded had to be reestablished as soon as the water receded. Finally,

mathematics was also used to calculate quantities of grain, the ratio of grains to output for bread and beer known as the *pefsu*, forecasting productivity, and calculating taxes.

The practicality of mathematics found on currently existing papyri, sources that were used in educating scribes, might lead to a premature conclusion that this is the only type of mathematics in ancient Egypt. It is important to note that while Egyptian mathematical activities were highly practical, some recorded problems were not. For instance, calculating circular pieces of land, while outside practical applications, were extensions of more common land-measuring problems. In this case, Egyptians did not use the concept of *pi* to calculate the areas of circles but used a formula to give sufficient approximations. What they did was to subtract $1/9$ of the diameter from itself and square the answer, resulting in a good approximation of the area. This is an example of practical problems giving rise to more theoretical investigations.

Mesopotamian

This civilization is also referred to as *Babylonian*, although the city of Babylon was not always the center of culture in this region. This area was called *Mesopotamia*, meaning country between two rivers, because of the rivers Tigris and Euphrates that bordered it. Owing to this water source, the area became viable for agriculture and it earned the name Fertile Crescent. It also was open to invasions and had multiple rulers from different regions. Unlike the Egyptian civilization, the Mesopotamian area was composed of various independent city-states. The cuneiform or wedge-shaped writing system that developed from this area possibly antedates the Egyptian hieroglyphs and may have been the earliest form of written communication. These were impressions made on clay tablets, making them more durable than the Egyptian papyri.

Unlike Egyptian mathematics, there are more artifacts with mathematical text that have survived and have been excavated from this region. Through the study of ancient problems, it becomes evident that ancient Mesopotamian scribes used their mathematical knowledge in various areas such as land measurement, business calculations such as silver and grain exchanges, and agriculture. There also are examples that demonstrate mathematical

inquiries and abstractions beyond everyday specific practical applications. For example, the Mesopotamians knew how to solve three-term quadratic equations. What is called now as the Pythagorean theorem was also widely used. It is unknown whether these algebraic activities were for practical purposes or for general understanding, but many historians believe there is justification to say that they went beyond the practical. There might be awareness of these concepts hidden in specific practical problems. For instance, in some word problems, concepts of length and width might have been interpreted as variables, equivalent to the x and y symbols used in modern mathematics.

The numeration system from this region was sexagesimal. This might have evolved because it was easier to do calculations with it. The sexagesimal numbers are easier to divide by two, three, four, five, six, 10, 12, 15, 20, and 30, making it convenient for commercial-related arithmetic. The system used was also positional, which means the placement of the number signifies that it is a multiple of different orders of magnitude. For example, in our current decimal system, the number 532 signifies that the 5 is 5 multiplied by 100, the 3 means 3 multiplied by 10, and 2 by 1. Although initially Mesopotamians did not have a symbol for zero and just left a blank for the empty spot, a symbol eventually was devised, consisting of two small wedges placed diagonally. They were able to expand this positional property for fractions; therefore, they had computational power similar to that of our modern decimal fractional notation. This made it easier to get more accurate approximations, such as for calculating the value of the square root of two. They had an algorithm for calculating any square root, which later was attributed to others, including the Greek scholar Archytas, Heron of Alexandria, and Isaac Newton. Their computational sophistication is also evident in the precalculated tables that were used by scribes, and which contained successive powers of a given number, almost like modern logarithmic tables; these, however, were used for specific problems and not for general calculations.

Chinese

Some historians believe that the Chinese developed their mathematics independently from other

civilizations in the ancient world. Before the forced unification of the region by the Qin dynasty in 221 B.C.E., there were many master scholar–student relationships that flourished, making possible the transmission of mathematical knowledge. After this period, the Chinese central government started employing intellectuals to serve it directly. Most intellectuals, including mathematics practitioners, were government workers. These scholars supported the government ideologically as both teachers and writers. Eventually, the Han dynasty replaced the Qin and established the centralized civil service examination system, still enlisting the most capable and literate men to be part of the government. With this process, the government controlled the ideologies that prevailed at that time. The dynasty privileged Confucian thought over all other schools and made this the official state ideology.

One of the necessary forms of expertise for a civil servant was the *suan*. Literally, this referred to counting rods used for arithmetic, but it also meant the practice of using them. The underlying system was decimal. *Suan* was not the most important skill government employees had, nor was it a separate area of intellectual inquiry. The Chinese at that time did not differentiate between the study of nature and the study of mathematics, and they investigated the connections between mathematics and areas such as physics, cosmology, astronomy, and music.

Two major treatises were written in ancient China, the *Zhou bi suan jing*, translated to “Arithmetic classic of the gnomon of Zhou” and the *Jiu zhang suan shu* or the “Nine chapters on mathematical procedures.” The later document contained 246 problems on surveying, business, engineering, agriculture, solutions of equations, and right triangles. It followed the problem-and-answer method also found in other ancient texts from other regions of the world. The method for calculating the areas of basic shapes such as triangles, circles, rectangles, and trapezoids were also discussed in this document. A significant section of the *Nine chapters* was on solutions to problems on simultaneous linear equations using both positive and negative numbers, something practitioners were accustomed to because they used two sets of rods, red and black, to denote negative and positive.

During the Han dynasty, *suan* remained an unimportant subject among the other fields of study. In fact, the two treatises written about it were categorized under astronomical texts. Mathematical inquiry, or creating a new method of *suan*, was not an important endeavor at that time. This was until the period of division, from 221 to 581 C.E., when the empire was broken apart into competing kingdoms. Suddenly, the ideologies from the past were rediscovered, some dealing with logic and mathematical concepts. This was the period when an intellectual named Liu Hui wrote a commentary about the *Nine chapters*, describing how it actually worked and adding discussions such as the correct calculation for the circumference of the circle. This reworking of the *Nine chapters* was a start of the re-blossoming of mathematics in ancient China.

Greek

The unique mathematical style that developed in the ancient Greek world was, as noted earlier in this entry, the axiomatic-deductive system, a way of mathematizing utilized in major ancient mathematics text such as *The Elements* by Euclid. This was not the mathematics practiced by the majority but only by a social elite who were more interested in theoretical matters—those mathematical ideas far removed from practical applications. Nonetheless, this is the approach adopted by modern mathematicians and the inherent structure of current mathematical writing. The Euclidian style was absent in earlier times and mathematical writings from that period implied that the reader was meant to understand abstract methods by dealing with actual cases. The practical mathematics problems were recipe-like, and rhetorical structures were evident. In the earlier periods of ancient Greek civilization and among practical mathematics practitioners, the concepts of definitions, proofs, and arguments were not known. Greek theoretical mathematics, which was exclusively geometric, only appeared toward the end of the 5th century B.C.E.

The common person's practical mathematics was the basis from which theoretical mathematics evolved over centuries. Euclidian-style mathematics appeared only in the later periods of Greek

civilization. Pebble arithmetic, similar to techniques using an abacus, was offered by practitioners-for-hire for various types of calculations. Not much is known about these professionals, but it is known that some Pythagoreans in 5th century B.C.E. Greece used their knowledge for semi-religious practices. In this period, there were also geometers who were hired to measure areas and volumes.

The Greeks adopted the literary and mathematical traditions of civilizations in the same region. Arithmetic knowledge came from Old Babylon, and fractional computation and geometry from Egypt. In fact, many ancient Greek writers such as Socrates and Aristotle attribute the beginnings of mathematics to the Egyptians. Aside from Mesopotamian and Egyptian mathematics, they also were able to transform the Phoenician writing system into their own. For example, Thales of Miletus (ca. 626–ca. 548 B.C.E.), a mathematician who made many discoveries, actually had ideas already known to Babylonians a millennium before. Another popular ancient mathematician, Pythagoras of Samos (b. 569 B.C.E.), traveled to Egypt, Babylon, and possibly India, where he learned various mathematical and religious ideas. Not surprisingly, mathematics and religion were intertwined within the Pythagorean school of thought. Number mysticism was an integral part of the Pythagoreans' beliefs, and numbers were elevated to a higher status. It was said that under them, the concepts of theoretical and practical mathematics, that which is for training the mind and that for real-life applications, were demarcated. These ideas were later promulgated by Plato (ca. 429–347 B.C.E.) when he distinguished between arithmetic as number theory for philosophers and logistic for businessmen and men of war.

The center of Greek theoretical mathematics was Athens for more than a century, until it moved to Alexandria in Egypt. In this city during the 5th century B.C.E., many mathematicians contributed profoundly to the shape of mathematical practice. Some of the important problems tackled during this period were the squaring of the circle, the duplication of the cube, paradoxes on motion, and ideas about infinity. Most of the mathematicians at this time were associated with the Academy of Plato in Athens. However, in 323 B.C.E., Alexander the Great died and the empire collapsed, leading to

the territories being divided and the center of mathematics moving to Alexandria. This was where intellectuals like Euclid, Archimedes, and Apollonius left their legacies that led to the more advances in mathematics. It developed in this period until it declined during under the Roman Empire, which was less hospitable to scholars, eventually moving its center to the Byzantine Empire.

MATHEMATICS, ENLIGHTENMENT

The Age of Enlightenment describes a philosophical and intellectual movement that took place during the 17th and 18th centuries. During this time, there occurred a shift in thinking toward reason, logic, and freedom, views that were supported, for example, by the rediscovery of earlier, mathematical texts. Logic, although not a new invention, having been much in use by the ancient Greeks, was now included in a worldview which argued that empirical observation could be used to reveal the true nature of the universe and the self. Enlightenment thinkers held that science could explain humankind, and that humanity's history had been marked by progress, a progress that could be continued if rational methods were followed. Enlightenment thinkers also believed that human character could be improved through education and reason, and that the universe was a functioning machine with the capacity for alteration. Enlightenment thinkers wanted not only to understand the world but also to change it for the better using reason and science.

Although there is no definitive starting point or ending point for the Enlightenment, it is generally supposed to be a 17th- and 18th-century phenomenon. Some historians give the English Civil Wars as key start dates for the philosophies of Enlightenment figures including the philosopher Thomas Hobbes, with the close of the era often attributed either to the death of Voltaire in 1778, or the beginning of the French Revolution in 1789.

The Enlightenment, coming as it did in the wake of the Renaissance, saw an unprecedented explosion in mathematical and scientific ideas across Europe. This is why the Enlightenment was also called the *Age of Reason*. Mathematics followed hard on the heels of the Copernican Revolution of the 16th century as well as the revolutionary discoveries made by Galileo, Tycho Brahe, and Johannes Kepler, Kepler's exploration of the solar system having led to Kepler's mathematical laws of planetary motion. The invention of the logarithm by John Napier early in the 17th century made a big contribution to the disciplines of astronomy and mathematics by rendering some formerly complex calculations far simpler. In fact, this was one of the most significant mathematical developments of the time, paving the way for the innovations of Kepler and Newton. French astronomer and mathematician Pierre Simon Laplace working much later, in the 19th century, noted that Napier had halved the work of astronomers with his groundbreaking developments.

Early Enlightenment Mathematics

René Descartes (1596–1650) is often considered a leading figure of the enlightenment. A metaphysician, mathematician, and natural philosopher, he was not only responsible for changing the course of philosophy but is also considered one of the earliest Enlightenment mathematicians, his main contributions being analytical geometry and the theory of vortices. For Descartes, analytical geometry is not simply concerned with the application of algebra to geometry, as set forward by Archimedes and others. Descartes's form of analytic (also called *Cartesian*) geometry uses algebra to describe geometry. His method of representing unknowns in equations using x , y , and z and *knowns* as a , b , and c was to become the norm. He also pioneered the standard notation that makes

use of superscripts to illustrate the powers or exponents, for example, in squared numbers. He was the first mathematician to assign algebra a fundamental place in our system of knowledge and believed that algebra's function was to automate and mechanize reasoning, in particular reasoning about unknown or abstract quantities.

Descartes's understanding of algebra was profound. He proposed that the number of distinct roots of an equation is equal to the degree of the equation. He was also willing to consider negative (he termed them false roots) and imaginary roots. He developed a rule for determining the number of positive and negative roots in an equation, which became known as *The Rule of Descartes*. The rule states that an equation can have as many positive roots as it contains changes of sign, from + to – or from – to +; and as many negative roots as the number of times two + signs or two – signs are found in succession.

In *La Geometrie* (1637), Descartes outlined his revolutionary method for geometrical problem-solving, referred to as his *geometrical calculus*. He offered innovative algebraic techniques for analyzing geometrical problems and novel ways of understanding the connection between the construction of a curve and its algebraic equation. He also proposed an algebraic classification of curves based on the degree of the equations used in the representation of the curves. During Descartes's time, mathematicians were battling with questions surrounding geometrical proofs, especially with regard to the criteria for identifying curves. In respect of this *La Geometrie* had a huge impact.

Descartes established analytic geometry as a way of visualizing algebraic formulas. He developed a coordinate system as a way to locate points on a plane. The coordinate system comprises two perpendicular lines called *axes*. The vertical axis is designated as the *y* axis, and the horizontal axis is designated as the *x* axis. The intersection point of the two axes is called the *origin*, or point zero. The position of any point on the plane can be identified by locating how far, perpendicularly from each axis, the point lies. The position of the point in the coordinate system is specified by its *x* and *y* coordinates. This is written as (x, y) . The coordinate system is also known as the *Cartesian coordinate system*, after the Latin version of the name Descartes.

Descartes created the coordinate system to locate points on a plane, but the system later evolved into what we call *analytic geometry*. The basic principle of analytic geometry is that all pairs of values that satisfy the equation are coordinates of points on a curve. Conversely, all points on the curve have coordinates that satisfy the given equation *y*. Analytic geometry gives us the means to graphically express the relationship between two variables that are functionally related to each other. Described as a sort of *acid test* of the validity of a physical law or theorem, its coordinate system has had a huge impact, enabling analytic geometry to be applied to a wide variety of disciplines including physics, chemistry, economics, astronomy, and sociology. On this basis, Descartes has been described as having renovated a whole domain of human thought.

Foundational Mathematics

One of the most influential works of the early Enlightenment was Isaac Newton's *Principia Mathematica* (often referred to simply as the *Principia*). This book, published in 1687, is considered one of the most influential works in the history of science, and it would continue to dominate scientific views of the universe for centuries to come. Although it remains in the public consciousness largely owing to its famous explanation of the force of gravity—and to the apocryphal story of its author's having derived the principle when, sitting under an apple tree, he its fruit falling to the ground—Newton was a consummate mathematician and greatly influenced the path of mathematical development. He pioneered a new approach to mathematics, that of infinitesimal calculus, a calculus based on earlier work by mathematicians including Descartes, Pierre de Fermat, and fellow Englishmen Isaac Barrow and John Wallis. Unlike the static geometry of the Greeks, calculus enabled mathematicians to make sense of motion and dynamic change, including such things as the orbits of planets and the motion of fluids. Newton discovered that it was relatively easy to represent and calculate the average slope of a curve (e.g., the increasing speed of an object on a time–distance graph). However, since the slope of a curve constantly varies there was no way to identify the exact slope at any specific point on it—that is, to

work out the slope of a tangent line to the curve at that particular point. Using intuition, we can approximate the slope at a particular point by taking the average slope or *rise over the run* of increasingly smaller segments of the curve. When the segment of the curve under consideration approaches zero in size (where there is an infinitesimal change in x), the calculation of the slope gets nearer and nearer to the exact slope at a point.

Thus, Newton calculated a derivative function $f'(x)$ which gives the slope at any point of a function $f(x)$. This method of calculating the derivative of a curve or function is termed *differential calculus*, or differentiation. Having established the derivative function of a particular curve, it is relatively straightforward to calculate the slope at any particular point on that curve by inserting a value for x . The opposite of differentiation is integration, or *integral calculus*, and together these two perform the main operations of calculus. Newton's Theorem of Calculus states that differentiation and integration are inverse operations. If a function is firstly integrated and subsequently differentiated (or the other way around), then the original function will be retrieved.

Theory of Calculus

Gottfried Wilhelm Leibniz (1645–1716) also occupies a very important place in the history of mathematics. A contemporary of Newton, he developed a theory of calculus very similar to Newton's and in fact was the first to publish his work, which led to a certain amount of controversy over who was first to develop the theory. History in fact finally favored Leibniz's notation, which is still used by mathematics today. Leibniz was also involved in reviving the ancient method of matrices as a way of solving equations, which involved arranging linear equations in an array so they could be manipulated to find a solution.

This paved the way for the linear algebra of Carl Friedrich Gauss (1777–1855). He pioneered the development of the binary system and introduced notions of self-similarity, as well as the principle of continuity, foreshadowing the mathematical discipline of topology. Leibniz also worked on a practical calculating machine, which used the binary system, and could multiply, divide, and extract roots. This extraordinary

machine was the forerunner of today's computers. Leibniz is credited with developing the binary number system. He also worked extensively in the area of logic, even though he published nothing in his lifetime on the subject. In working drafts, we can see his setting out the principal properties of what are now known as *conjunction*, *disjunction*, *identity*, *negation*, *set inclusion*, and the *empty set*.

Toward the end of the 17th century, the focus shifted to the followers and disciples of Newton and Leibniz who applied their ideas on calculus to solving problems in astronomy, physics, and engineering. One name in particular stood out during this time, that of Bernoulli, the surname of two brothers, Jacob and Johann, who influenced several generations of outstanding mathematicians. They advanced Leibniz's theory of infinitesimal calculus, developing a calculus known as the *calculus of variations* by generalizing and extending it. The Bernoulli brothers also worked on Pascal and Fermat's earlier probability and number theory.

The Bernoullis lived in Basel, Switzerland, also hometown to influential Enlightenment mathematician Leonhard Euler. The brothers corresponded with Leibniz and were among the first mathematicians to study and comprehend infinitesimal calculus, as well as to apply it to new problems. They were also instrumental in helping to make calculus the cornerstone of mathematics, something which remains the same today. As well as being disciples of Leibniz, however, the Bernoullis made important contributions of their own. They concerned themselves with the problem of designing a sloping ramp, so that a ball could roll from top to bottom in the shortest time. Johann Bernoulli was able to demonstrate via calculus that neither a straight ramp nor a curved one with an extreme initial slope were the optimal answer. In fact, a less steeped curve, or kind of upside-down cycloid, would allow for the fastest descent of the ball. This application illustrated the use of the calculus of variations developed by the Bernoullis, which has been found useful in multiple areas including engineering, architecture, and finance. In 1713, Jacob Bernoulli's *The Art of Conjecture* was published, after his death. This consolidated existing probability theory and set out his theory of permutations and combinations, as well as some

aspects of Bernoulli number theory. He also produced papers on transcendental curves and was first to develop a technique for solving separable differential equations. Polar coordinates, which describe the location of points in space using distances and angles, are also included in his list of accomplishments, and he was the first mathematician to refer to the word *integral* as it related to the area under a curve.

Jacob Bernoulli was also responsible for discovering the approximate value of the irrational number e . He made this discovery while examining compound interest on loans. Compounded at 100% interest per year, £1 becomes £2 after 1 year. When compounded half-yearly, it produces £2.25; quarterly, £2.44; monthly £2.61; weekly £2.69; daily £2.71, and so on. If interest were to be compounded on a continual basis the £1 would tend toward a value of £2.7182818 after 1 year, and this value became known as e . In algebraic terms, this is the value of the infinite series $(1 + \frac{1}{1})^1 \cdot (1 + \frac{1}{2})^2 \cdot (1 + \frac{1}{3})^3 \cdot (1 + \frac{1}{4})^4 \dots$

Early 18th-Century Mathematics

Euler was a prolific mathematician of the renaissance. During his lifetime, he produced no less than 900 completed works, on average one mathematical paper a week. His interests in mathematics ranged from geometry and calculus to trigonometry, algebra and number theory. Much of the mathematical notation we use today originated with Euler, including e , i , $f(x)$, Σ and the use of a , b , and c as constants and x , y , and z as unknowns. He also attempted to standardize other symbols including π and the trigonometric functions. Euler's work helped to turn mathematics into an international subject which invited collaboration from mathematicians right across the world.

Euler was famous for producing what is considered one of the most beautiful mathematical equations of all time $e^{i\pi} = -1$, generally known as *Euler's Identity*. This equation combines calculus, arithmetic, complex analysis, and trigonometry into a remarkable mathematical formula. Another of his discoveries, Euler's Formula, also demonstrated the deep relationships between complex numbers, trigonometry and exponentials.

Euler's reputation was sealed by the discovery of the calculation of infinite sums in 1735. The

Bernoulli had tried but failed to solve this problem, so it had become known as the *Basel problem*. When asked what the precise sum of the reciprocals of the squares of all the natural numbers to infinity was, that is, $\frac{1}{1^2} + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} \dots$ (a zeta function using a zeta constant of 2), Daniel Bernoulli stated that he believed it to be approximately $1\frac{3}{5}$. Euler's method, however resulted in an answer of $\pi^2/6$. He also demonstrated that the infinite series was equivalent to an infinite product of prime numbers. This identity was later to stimulate the investigation of complex zeta functions by Bernhard Riemann.

In the same year, 1735, Euler solved the logical and intransigent mathematical problem of the Seven Bridges of Königsberg. This enduring problem had remained unsolved for many years. The ancient city of Königsberg in latter-day Prussia was set on two sides of the Pregel River, and two islands between the banks were connected to each other and to the mainland by seven bridges. The problem was to identify a route through the city that would cross each bridge no more than once. Euler proved that there was in fact no solution to the problem. In doing this, he made a conceptual leap. This was in pointing out that the choice of route within each landmass is irrelevant, and that the only important element of the problem was in the sequence of bridges crossed. He thereby reformulated the problem abstractly, replacing land masses with abstract nodes, and bridges with abstract connections. The result was a mathematical structure called a *graph*; that is, a pictorial representation comprising a number of points (vertices) connected by arcs, or nonintersecting curves which can be distorted without affecting the graph. In carrying out the problem in this way Euler could deduce that, since the four land masses in the original problem are touched by an odd number of bridges, instances of a walk crossing each bridge only once results in a contradiction. If, on the other hand, Königsberg had one bridge fewer, thus an even number of bridges leading to a piece of land, a solution would have been possible.

Euler's totality of theorems and methods was huge. They include the demonstration of geometrical properties, for example, Euler's Line and Euler's Circle, new methods for solving quartic equations, the Prime Number Theorem, proofs of

Fermat's theorems and conjectures, the discovery of 60-plus amicable numbers, the calculus of variations and much more.

Development of Analysis, Number Theory, and Mechanics

Joseph Louis Lagrange (1736–1813) was a significant figure in Enlightenment mathematics, making contributions to the fields of analysis, number theory and mechanics. Lagrange was only nineteen when he solved the isoperimetrical problem—a problem which had been a subject of mathematical discussion for over half a century. He effected his solution by enunciating the principles of the calculus of variation and sent the answer off to Euler. Euler was so impressed that he withheld a paper he had been working on in the same area, so that Lagrange could complete his work and claim the invention of a new calculus. This placed Lagrange in the top rank of mathematicians then living. In 1758, Lagrange joined a society known as the *Turin Academy*, and it is in the volumes of its transactions that the bulk of his work can be found. In the first volume, he provides insights into the theory of the propagation of sound, indicating a mistake made by Newton. He obtained the general differential equation for the motion and integrated it for motion in a straight line. He also provides insights into recurring series, probabilities, and the calculus of variations. In the second volume, Lagrange sets forth a theory on the notation of the calculus of variations, illustrating its use by deducing the principle of least action, and by the solutions to several problems in dynamics. The third volume involves Lagrange's solution to dynamical problems using the calculus of variation along with papers on integral calculus. He also addresses the general differential equations of motion for bodies moving under mutual attraction.

Lagrange completed several works on algebra discussing representations of integers by quadratic forms and on algebraic forms in general. His papers of 1770 and 1771 put forward a general process for solving an algebraic equation of any degree via the Lagrange Resolvents. This method is significant for exhibiting the existing formulas for solving equations of second, third, and fourth degrees as manifestations of a single principle, a

method that formed the basis of Galois theory. In 1773, Lagrange proved the expression for the volume of a tetrahedron. Lagrange was also interested in number theory and was the first to prove that Pell's equation was incorrect.

It was for his seminal work on analytical mechanics, *Mecanique Analytique*, that Lagrange became best known. Written in Berlin in 1788, this offered the most comprehensive treatment of classical mechanics since Newton, forming the basis of mathematical physics in the 19th century. Lagrange based his research in mechanics on his own calculus of variations in which certain properties of a mechanistic system are inferred by considering the changes in a sum, or integral, that result from conceptually possible—or virtual—displacements from the path that describes their actual history of the system. From this, Lagrange identified independent coordinates necessary to the specification of a system comprising a finite number of particles, or *generalized coordinates*.

Lagrange later lectured at the École Polytechnique and in 1797 published papers on “Theory of Analytic Functions,” and “*Leçons sur le calcul des fonctions*,” or “Lessons on the Calculus of Functions.” These provided the basis of the first real textbooks on functions. In them, Lagrange attempted to substitute an algebraic foundation for the foundation of calculus, which was at that time problematic. Although he was ultimately unsuccessful his work spurred others on to develop the modern analytic foundation.

During his lifetime Lagrange was also heavily involved in the process of formulating new standard units of measurement at the close of the 18th century. It was Lagrange's influence that resulted in the final choice of the unit system of meter and kilogram and largely due to him that decimal subdivision was accepted in 1795 by the Commission for weights and measures in France.

Later Renaissance Mathematics and the Theoretical Explanation of the Solar System

Pierre Simon Laplace (1749–1827) was a French mathematician and astronomer best known for his investigation into the stability of the solar system. Laplace applied Newton's theory of gravitation to the solar system and managed to account for all observed deviations of the planets from

their theoretical orbits. He also demonstrated the usefulness of probability in the interpretation of scientific data.

It was in 1773 that Laplace began his life's work by undertaking to solve a particularly perplexing problem—that of Jupiter's orbit. Jupiter's orbit appeared to be shrinking continuously while that of Saturn expanded. The mutual gravitational interactions in the solar system were highly complex and seemed impossible to apply a mathematical solution to. For this reason, even Newton had concluded that divine intervention was required from time to time in order to preserve the system's equilibrium. Laplace set forth the invariability of planetary mean motions (average angular velocity) in 1773, and this was the first and most significant step since Newton toward establishing the stability of the solar system. Laplace examined the perturbations, or mutual gravitational effects, of planets and succeeded in proving that the eccentricities and inclinations of planetary orbits will always mutually remain small, self-correcting and constant.

Laplace applied quantitative methods to a comparison of living and inert systems. In 1780, along with Antoine-Laurent Lavoisier in 1780, and aided by a self-developed ice calorimeter, he illustrated that respiration was a form of combustion. In 1784 and 1785, Laplace worked on the subject of attraction between spheroids, work which resulted in his identification of the potential function of later physics. He examined the problem of attraction and discovered that the attractive force of a mass upon a particle, no matter the direction, can be obtained by differentiating a single function. This laid the mathematical foundation for the scientific study of magnetism, heat, and electricity.

In 1797, Laplace managed to remove the final remaining anomaly in the theoretical description of the solar system. He announced that lunar acceleration depends on the eccentricity of the earth's orbit. Whereas the mean motion of the moon depends on the gravitational attraction between the moon and Earth, this attraction is slightly diminished by the Sun's pull on the moon, solar action which depends itself on changes in the eccentricity of the earth's orbit, which is in turn affected by the perturbations of the other planets. The result is that the mean motion of the moon is accelerated so long as the earth's orbit becomes more circular. When the opposite happens, the

motion is retarded. This inequality is not truly cumulative, according to Laplace, but is of a period running into millions of years. Thus, Laplace removed the last threat of instability from the theoretical explanation of the solar system.

In 1796, Laplace published *The System of the World*, which was an exposition of his work in celestial mechanics. The book also included his nebular hypotheses. His *Celestial Mechanics*, which appeared between 1798 and 1827, summarized the results of his mathematical developments and application of the law of gravity. By calculating the motions of the planets, their satellites and perturbations, he devised a way of calculating the motions of the planets.

Laplace also published a popular work, *A Philosophical Essay on Probability*, which introduced his theory of probability to the masses. In it, he described the tools he had invented for mathematically predicting the probabilities that certain events will happen in nature. He applied his theory not just to ordinary events of chance but to the inquiry into the causes of phenomena, future events, and statistics. He also stressed its importance for astronomy and physics. This work also became renowned for its inclusion of Laplace's Central Limit Theorem in which Laplace proved that the distribution of errors in large samples of data taken from astronomical observations can be approximated by a normal distribution. A normal distribution is also known as a *Gaussian distribution* and is the most common distribution factor for randomly generated variables.

Laplace, like Lagrange, escaped imprisonment during the French Revolution, and was also involved in the organization of the metric system.

The Greenhouse Effect

Joseph Fourier (1768–1830) was a French mathematician and physicist renowned for illustrating how the conduction of heat in solid bodies could be analyzed in terms of infinite mathematical series. This became known as the *Fourier series*. Fourier's theory was the first accurate scientific theory to explain the diffusion of heat. Fourier was also known for his discovery of the greenhouse effect.

Fourier first developed an interest in mathematics at an early age and read Bezout's *Cours de*

Mathematiques at the age of just 14. In 1822, Fourier presented papers on the flow of heat in *Theorie analytique de la Chaleur* (*The Analytic Theory of Heat*). Based on Newton's law of cooling, Fourier deduced that the flow of heat between two adjacent molecules is in direct proportion to the minute difference in their temperatures. In his explanation, Fourier took three different aspects, one mathematical and the others physical. From a mathematical point of view, Fourier put forward the theory that any function of a variable, whether continuous or discontinuous, could be expanded in a series of sines of multiples of the variables. This was actually incorrect; however, his observation that some discontinuous functions equal the sum of infinite series was a revelation. Of the two physical elements of the theory, the proposal of his partial differential equation for conductive diffusion of heat is still taught to mathematical physicists today.

Fourier also began work on determinate equations, a work which was later completed by Claude-Louis Navier in 1831. In this, Fourier demonstrated his position on the roots of an algebraic equation. His work on the concept of the greenhouse effect rested on his calculation that the Earth, taking into consideration its size and distance from the sun, should be much colder than it is if warmed only by the effects of solar radiation. He suggested that a large portion of the additional heat received by the Earth was a result of interstellar radiation, a concept of the atmosphere that became known as the *greenhouse effect*.

Legacy of the Enlightenment Mathematicians

The mathematicians of the Enlightenment played a pivotal role in influencing many generations to come. They were responsible for the development of all main modern branches of mathematics as well as that of numerous other important disciplines in science. Isaac Newton, in addition to inventing the calculus, was credited with having invented the reflecting telescope and proposing a theory of light and color, developing three laws of motion, and devising the laws of universal gravitation. René Descartes was not only a creative mathematician but also an important scientific thinker. Descartes' mode of problem-solving and his

mathematical results were new and influential. There is also a philosophical significance to his work. By blending algebra and geometry and taking a novel approach to the geometrical status of curves, he made a significant contribution to ongoing philosophical debates surrounding then current mathematical practices.

Descartes can be credited with not only coframing the laws of refraction but also for developing an empirical account of a rainbow. More importantly, he offered us a new vision of the world, a world of matter possessing few material properties, and an immaterial mind, directly related to the brain. Descartes was a theorist who set the agenda for new directions in thought.

Joseph-Louis Lagrange made significant contributions to science and mathematics and transformed Newtonian mechanics into a branch of analysis. He also produced many important papers on problems in astronomy, and the mechanics of solids and fluids.

Pierre Simon Laplace was central to the development of mathematical astronomy and was also the first person to propose the existence of black holes. In addition, he was a central force behind systemizing probability theory, a theory that was to lay the groundwork for Bayesian statistics, and he pioneered the study of the speed of sound.

Joseph Fourier, an inspired mathematician, was a close friend of Napoleon Bonaparte and accompanied him on his Egyptian expeditions. Fourier helped to collate the scientific and literary discoveries they made during their time in Egypt. He was also later charged with constructing the new highway that ran from Grenoble to Turin, and it was at Grenoble that his mind turned to the important work he was to do on the propagation of heat.

MATHEMATICS, MIDDLE AGES

Between the 5th and 15th centuries C.E., many significant scholarly developments occurred in the field of mathematics. This period has come to be termed the *Middle Ages* by contemporary historical researchers, and the intellectual achievements during this era, also referred to as the *medieval period*, have provided critical foundations for our modern mathematical and scientific understandings of the world. Four different cultural systems in particular experienced substantial mathematical progress during this millennium: Arabic culture, Chinese culture, European culture, and Indian culture.

These four cultures advanced their understandings of mathematics in contrasting ways. Some, such as the mathematicians of the Chinese and Indian cultures, developed their mathematical systems largely independent of outside influences, while others developed their systems based on the intellectual foundations provided by other cultures, in the way that European mathematicians adopted many elements from Arabic mathematics. Furthermore, these cultures progressed at different rates in their technical comprehension of the elements of mathematics. Chinese advancements in mathematics peaked during the 13th century, while the so-called Golden Age of Indian mathematics is said to have spanned between the 5th and 12th centuries. Likewise, Arabic mathematics in the Middle Ages climaxed between the 9th and 13th

centuries, whereas European mathematics peaked later, between the 12th and 15th centuries.

Examining the mathematical accomplishments of the Middle Ages can provide contemporary researchers with conceptual genealogies that will help to illuminate how we, in today's global civilization, have arrived at our modern mathematical theories of the universe. Although some concepts of the mathematicians of the Middle Ages may seem rudimentary or strange by modern standards, they have served as theoretical stepping-stones that scholars worldwide have used to help further our mathematical understanding. More specifically, the mathematicians of the Middle Ages made significant and novel advancements in the fields of algebra, geometry, and trigonometry, and many of their ideas are still taught today in classrooms worldwide.

Significant Arabic Mathematicians of the Middle Ages

Muhammad ibn Musa Al-Khwarizmi (780–850 C.E.) was a prolific Persian scholar whose range of knowledge extended over many fields of study, including algebra, astronomy, geometry, and translation. In a text he called *On the Calculation With Hindu Numerals*, Al-Khwarizmi translated into Arabic some of the theoretical works of the Indian mathematician Brahmagupta, and thus was responsible for being the first to introduce the Hindu numeration system and its concept of decimal places to the Arabic-speaking world, which European thinkers later translated from Arabic into Latin.

At some point during the 9th century, Al-Khwarizmi became the director of the prestigious academy known as the *House of Wisdom*, which was located in what is modern-day Baghdad, Iraq. It was during his time that Al-Khwarizmi developed and completed his most significant mathematical work, *The Compendious Book on Calculation by Completion and Balancing*. In this text, Al-Khwarizmi initiated the field of algebra by detailing the processes of first- and second-degree equations and how they could be practically applied.

Born in Baghdad, where he spent most of his life, Abu Bakr Muhammad ibn Hassan Al-Karaji (953–1029 C.E.) was another gifted Persian mathematician and engineer. Al-Karaji was interested

in applying his understanding of Arabic and Hindu mathematics to practical matters. For example, he wrote a technical manual called the *Book of the Extraction of Hidden Waters*, which made use of mathematics to describe the proper ways in which to dig wells and create canals.

Al-Karaji's most prominent work is his extensively studied *Al-Fakhri* (*The Glorious*, a book of algebra), in which he details arithmetic operations regarding polynomials, such as the procedures involving their addition, multiplication, and subtraction. In his other various mathematical works, Al-Karaji proved the binomial theorem, developed an algebraic usage of exponents, and attempted to differentiate algebra from geometry. Another important aspect of Al-Karaji's mathematical legacy is that he was the first to use the process of mathematical induction as a method of providing proof.

Hailed as one of the most preeminent scholars of the past two millennia, the Persian Abu Rayhan Al-Biruni (973–1048 C.E.) was expertly versed in a wide variety of fields, including astronomy, geology, history, linguistics, mathematics, physics, and theology. In the course of his long lifetime, Al-Biruni wrote prodigiously on the field of mathematics, publishing over 90 texts regarding mathematical subjects.

Perhaps Al-Biruni's most significant intellectual contribution to the field of mathematics is his work regarding mathematical geography as detailed in his masterwork, the *Determination of the Coordinates of Places for the Correction of Distances Between Cities*. In this text, Al-Biruni provides a process for which to determine latitudinal and longitudinal coordinates. To offer a practical application of this process, Al-Biruni utilized trigonometry to ascertain the direction of Mecca from the city in which he was then staying, Ghazna. Such an application allowed Al-Biruni to defend the importance of mathematics against the theological critiques of religious scholars of his era.

Significant Chinese Mathematicians of the Middle Ages

Yang Hui (1238–1298 C.E.) was a Chinese mathematician who hailed from the city that in modern times is known as *Hangzhou*. During his lifetime, Yang Hui wrote several texts on the topic of

mathematics, such as the widely studied works *Detailed Analysis of the Mathematical Rules in the Nine Chapters* and his *Fundamental Mutual Changes in Multiplication and Divisions*. However, Yang Hui is perhaps most widely renowned for his presentation of the concept known as *Yang Hui's triangle*, which provides a blueprint for binomial expansion calculations.

In fact, Yang Hui's triangle describes the same exact mathematical concept as Pascal's triangle, which Blaise Pascal organized four centuries later. As detailed in his various mathematical treatises, Yang Hui also made many other novel contributions to the field of Chinese mathematics, including processes for solving quadratic equations and discovering cube and square roots.

Born in the city of Yan-Shan, the Chinese mathematician Chu Shih-chieh (1249–1314 C.E.) is hailed by Eastern and Western scholars alike as one of the greatest mathematical minds to have ever lived. Such a statement becomes even more impressive when contrasted with the fact that Chu Shih-chieh is known to have written only two mathematical texts in his lifetime, his *Introduction to Mathematical Studies* and the *True Reflections on the Four Unknowns*.

For nearly 30 years, Chu Shih-chieh traveled copiously throughout both the northern and southern regions of China, and during his travels, he taught his mathematical ideas to countless students. Chu Shih-chieh made many significant developments to the field of mathematics, such as his method for calculating equations that involved decimals and fractions. He also developed new procedures for finding areas and volumes, solving polynomial equations, and calculating concurrent equations. In the centuries following his death, his two mathematical works became extremely popular theoretical textbooks in the territories of China, Japan, and Korea.

Significant European Mathematicians of the Middle Ages

Born in Rome to a family with a prestigious ancient lineage, Boethius (480–524 C.E.) was a highly educated Roman scholar. In fact, Boethius was so unusually well-educated for his time that contemporary researchers suspect that he likely studied in the famous scholastic cities of

Alexandria and Athens during his youth. Boethius's extensive education allowed him to translate the mathematical works of Euclid and Nicomachus into Latin, and his translations of these works served as the main mathematical textbooks available to Europeans until the 12th century.

Boethius's main mathematical text, *Arithmetic*, was based on Nicomachean modular arithmetic and served to introduce European audiences to Pythagoras's theories regarding natural numbers. Boethius's *Arithmetic* provided a large portion of the study materials which were utilized in European monasteries' educational courses of the era, the *quadrivium*, so-called, which was focused upon the fields of arithmetic, astronomy, geometry, and music theory. For this reason, Boethius was a critical forerunner of European mathematics.

Adelard of Bath (1080–1152 C.E.) was a prolific English scholar who is credited with being the first to introduce particular elements of Arabic, Greek, and Hindu mathematics to European thinkers. Adelard traveled widely in Europe and Central Asia during his lifetime, and during his travels, he mastered the Arabic, Greek, and Latin languages. His extensive knowledge of languages allowed him to translate important Arabic mathematical texts, such as the algebraic works of Al-Khwarizmi, into the European *lingua franca* of the period, Latin.

Furthermore, with certain elements of Arabic mathematics having been influenced by Hindu systems, Adelard is recognized for introducing the Hindu numeral system to Europe. Beyond these feats, Adelard wrote treatises regarding the proper usage of abacuses and astrolabes. Upon returning to Europe after his studies in Central Asia, Adelard settled in Laon, northern France, and began to give local lectures on the topics of Arabic mathematics and Arabic philosophy.

The Italian researcher Gherard of Cremona (1114–1187 C.E.) was an industrious translator of Arabic scholastic texts, many of which dealt with a variety of mathematical subjects. After becoming dissatisfied with the education he had received in Italy, Gherard moved to Toledo, Spain, with the precise intention of learning the Arabic language in order to read and study Arabic academic texts.

After mastering the Arabic language in Toledo, Gherard set out to translate as many Arabic scholastic books into Latin as he possibly could; consequently, he translated more than 80 Arabic texts

into Latin, of which the most significant were works concerning geometry and mathematics, such as the Arabic mathematician Ahmed ibn Yusuf's research regarding ratios. For his prodigious work in Arabic translation, Gherard is considered by modern historians as having been one of the fundamental conduits of Arabic mathematical concepts into European culture.

Leonardo Pisano Fibonacci (1170–1250 C.E.) in contemporary times is regarded as being perhaps the most brilliant of the European mathematicians of the Middle Ages. Born in Pisa, Italy, and educated in the Algerian region of North Africa, Fibonacci quickly realized that the Arabic–Hindu numeration system was vastly more efficient than the Roman system he had previously been exposed to. After completing his travels in North Africa, Fibonacci returned to Pisa and began work on a series of important mathematical texts.

The first of these works was Fibonacci's well-known *Book of Calculations*, in which Fibonacci expounds upon Arabic algebra and the Arabic–Hindu decimal place system. In this text, Fibonacci also details the famous *Fibonacci sequence*, which is a sequence of numbers in which each number in the series is the sum of the two numbers that precede it. Another of Fibonacci's famous mathematical works is his *Practice of Geometry*, wherein he presents a large assortment of geometrical problems and then proceeds to solve them using theorems derived from the ideas of the ancient Greek master, Euclid. These two works proved critical in the development of European mathematical understanding during the Middle Ages.

Born near modern-day Königsberg, Germany, the German polymath Regiomontanus (1436–1476 C.E.) was an expert in the fields of astronomy, mathematics, and translation. After coming into contact with a fragment of Diophantus's famous treatise, *Arithmetica*, Regiomontanus began a lifelong foray into the study of mathematics. As a result of his intense interest in astronomical topics, Regiomontanus began to develop trigonometrical procedures to aid his studies on astronomy.

In his work, *On Triangles of Every Kind*, Regiomontanus systematically develops a system of trigonometry. In this text, Regiomontanus describes and details concepts such as arcs, chords, circles, equality, ratio, the sine function, and quantity, and wherein he also declares more than 50

theories regarding geometry. Regiomontanus's work on trigonometry was therefore critical in providing European audiences with novel methods for solving triangles related problems.

Significant Indian Mathematicians of the Middle Ages

Hailing from Bhinmal, India, Brahmagupta (598–670 C.E.) was an astronomer and mathematician who became one of the most important Indian mathematicians of the Middle Ages. At some point in his adulthood, Brahmagupta became the director of the Ujjain astronomical observatory, which at the time was India's academic and mathematical epicenter. While at Ujjain, Brahmagupta wrote some of his most significant mathematical texts, such as his *The Opening of the Universe* and his *An Astronomical Treatise*.

In these works, Brahmagupta develops theories regarding algebra, the computation of square roots, latitudes, longitudes, and quadratic equations, but he is perhaps most famous for his novel ideas concerning the concept of zero. Brahmagupta described how the number zero is created when a number is subtracted from itself. He also detailed what occurs when zero is added to, subtracted from, or multiplied by a number, and these notions formed arithmetic methods that are still in use in contemporary times.

Bhāskara II (1114–1185 C.E.) was an Indian astronomer and mathematician who is reported to have lived during the peak of Indian mathematics in the 12th century. He became the director at the same Ujjain astronomical observatory that his intellectual forerunner Brahmagupta had been a leader of several centuries earlier. In his lifetime, Bhāskara wrote three important mathematical texts: *The Beautiful*; *Seed Counting or Root Extractions*; and his *Head Jewel of Accuracy*.

Within these texts, Bhāskara covered numerous mathematical concepts, wherein he displayed a mastery over the usage of the number zero as well as negative numbers. In his mathematical studies, Bhāskara realized that there were logical inconsistencies in Brahmagupta's conception of dividing numbers by zero, and thus, he revised this notion in a way that is reminiscent of modern methods. Furthermore, he developed novel methods for

squaring numbers and wrote extensive definitions on arithmetic, astronomical, and geometric terms.

MATHEMATICS, 19TH CENTURY

During the 19th century, there was an unprecedented increase in the range and complexity of mathematical concepts. France and Germany, having been swept up in the tide of revolution that took over much of Europe during the latter part of the 18th century, produced some outstanding mathematicians. The two countries, however, took quite different approaches to the discipline. Post-revolutionary France under Napoleon put much focus on the practicality of mathematics. His reforms gave French mathematics a significant boost, as had been illustrated in the rise of the influential *three Ls* during the latter part of the 18th century: Joseph Louis Lagrange (1736–1813), Pierre-Simon Laplace (1749–1827), and Adrien-Marie Legendre (1752–1833).

The beginning of the 19th century saw Joseph Fourier's work on infinite sums reach fruition too. Fourier proposed the use of trigonometric functions as a tool for mathematical analysis. Fourier's series of periodic functions expressed as the sum of an infinite series of *sines* and *cosines* are still in use today in pure and applied mathematics. Fourier also helped to define what is meant by a function, although the definition in use today—that of defining it in terms of the corresponding elements of a domain and a range—is largely credited to German mathematician Peter Dirichlet.

This entry continues with discussions of the achievements of the most prominent figures in 19th-century mathematics—Évariste Galois, Carl Friedrich Gauss, Bernhard Riemann, George Boole, Georg Cantor, and Henri Poincaré—and, more briefly, the contributions of several other notable mathematicians of the period, including Charles Babbage, János Bolyai, Richard Dedekind,

Gottlob Frege, Nikolai Lobachevsky, Hermann Minkowski, August Ferdinand Möbius, Nicolò Paganini, George Peacock, and John Venn.

Évariste Galois

A towering figure in the world of 19th-century mathematics was Évariste Galois, who completed work in the late 1820s proving that there is no general algebraic method for solving polynomial equations of any degree greater than four. Galois's theory built on work previously been put forward a few years earlier by Norwegian mathematician Niels Henrik Abel. He also identified the impossibility of solving *quintic* equations, thereby solving a puzzle that had perplexed mathematicians for centuries. Galois paved the way for numerous developments including the origination of the field of abstract algebra, including algebraic geometry, rings, fields, group theory, modules, vector spaces, and noncommutative algebra.

Galois died in a duel at the age of 20, but in his short life, he had already made a name for himself in mathematical circles. At the age of 17, he began making important discoveries in the theory of polynomial equations (equations built from variables and constraints that used just the operations of addition, subtraction, multiplication, and non-negative whole number exponents). He succeeded, as noted earlier, in proving that it is not possible to have a formula for solving *quintic* equations. Quintic equations are polynomial equations with the term x to the power 5. Taking the work of Abel further, he also managed to prove that even more significantly, there are no algebraic methods in general to solve polynomial equations of any degree exceeding four. Galois derived these conclusions by examining whether or not the *permutation group* of its roots demonstrated a certain structure. Galois was the first mathematician to use the term *group* of permutations, thus setting the scene for the modern field of group theory. Galois's proof led to further definitive proofs or *disproofs* of the three classical problems set out by the ancient Greek philosopher Plato. This involved Galois in proving the impossibility of doubling of a cube and trisection of an angle. He also proved impossible the squaring of the circle.

Carl Friedrich Gauss

In Germany, by contrast, the influence of the great educationalist Wilhelm von Humboldt gave mathematics a rather different approach. Rather than simply supporting mathematics from a practical point of view, he encouraged the pursuit of pure mathematics for its own sake.

It was in this environment that Carl Friedrich Gauss came to prominence, a mathematician so esteemed that he was sometimes referred to as the *Prince of Mathematics*. In many ways, Gauss's ideas were ahead of their time, touching as they did on a wide variety of mathematical disciplines including geometry, number theory, algebra, calculus, and probability. One of the greatest mathematicians of all time, he is put in the same category as Archimedes and Isaac Newton.

Gauss was a veritable child prodigy, having already mastered and begun to criticize Euclid's geometry by the age of 12. His intellectual prowess attracted the attention of a wealthy benefactor, the Duke of Brunswick, who paid for him to attend the University of Göttingen, and it was here that he discovered several important theorems. Gauss was the first mathematician to identify any pattern in the occurrence of the prime numbers. This was a problem that had plagued mathematics since ancient times. Even though the occurrence of prime numbers appeared to be completely random, Gauss took an innovative approach to the problem by graphing the incidences of primes as the numbers increased. He noticed a trend or rough pattern whereby as the numbers increased by 10, the probability of prime numbers occurring reduced by a factor of roughly 2 (e.g., there is a one in four chance of there being a prime in the numbers one to 100, a one in six possibilities of getting a prime in the numbers one to 1,000, and a one in eight chances of a prime in numbers one to 10,000). Gauss was perfectly aware, however, that this method was only an approximation, and for this reason, he kept his early findings secret until he was far older.

At the age of 19, Gauss constructed what had previously been considered impossible—a regular 17-sided polygon, by using just a ruler and compass. This proved that a heptadecagon could be constructed geometrically, and this was a major mathematical advance even since the time of

Greek mathematics. In the same year, he formulated his prime number theorem on the distribution of prime numbers among the integers, proving that every positive integer can be represented as a sum of at most three triangular numbers.

Gauss proposed the first clear explanation of complex numbers and a clear exposition of the functions of complex variables early in the 19th century. Imaginary numbers, involving i , the imaginary unit equal to the square root of -1 , had been in use since the 16th century to solve previously unsolvable equations. Leonhard Euler (1707–1783) later completed ground-breaking work on these and on complex numbers but failed to provide a clear picture of how imaginary numbers could be connected to real numbers. Jean-Robert Argand (1768–1822) was one of the first mathematicians to use graphs to depict and interpret complex numbers, but Gauss was later responsible for popularizing this practice. He also went on to introduce the standard notation $a + bi$ for complex numbers. This subsequently resulted in the significant expansion of the theory of complex numbers. Gauss was also soon to prove what is now called *The Fundamental Theorem of Algebra*, which was not in fact directly related to algebra at all. The theorem illustrated that the theory of complex numbers is an algebraically *closed* system. This is in contrast to real numbers, and it holds that the solution to polynomials that have real coefficients can yield solutions in the complex number field.

In 1801, Gauss published *Disquisitiones Arithmeticae*, one of the most influential mathematical works ever written. This provided the foundation for modern number theory, provided an exposition of modular arithmetic, and presented the first proof of Euler's and Legendre's law of quadratic reciprocity.

Gauss retained an immense interest in theoretical astronomy for much of his life and was appointed the director of Göttingen's astronomical observatory, a post in which he served for many years. He predicted the position of the planetoid Ceres, a prediction that was quite different from those of his contemporaries, and he was later to be proven correct. To arrive at this prediction, Gauss had used one of the first applications of the least-squares approximation method.

Gauss also introduced what is now termed the *Gaussian distribution* into the areas of probability and statistics. This, along with the Gaussian function and the Gaussian error curve, illustrated how probability could be shown as a bell-shaped or *normal* curve, which peaks at the mean or expected value and then falls off quickly toward plus or minus infinity. This probability curve is fundamental to descriptions of statistically distributed data. He also performed the first systematic study of modular arithmetic drawing on modulus and integer division. Today, this is used in abstract algebra, number theory, computer science, and the visual and musical arts.

Another inquiry among the many that were pursued by Gauss was the shape of the Earth. Gauss had begun to speculate even on the shape of space itself, leading him to question one of the most central theories in the whole of mathematics, Euclidean geometry. The premises of Euclidean geometry lie on a flat, not curved, universe. Gauss, probably quite sensibly, decided not to publish his thoughts in this area, however, having seen what had happened to others, most notably Galileo, when they set forth avant-garde notions. He left the field open to János Bolyai and Nikolai Lobachevsky, who were willing to enter this controversial area.

Gauss was highly interested in the field of differential geometry, which is the field of mathematics that deals with curves and surfaces. He developed what became known as *Gaussian curvature*, which provides an intrinsic measure of curvature, which depends solely on how we measure distances on the surface rather than how they are embedded spatially.

Gauss was not only a consummate mathematician; he also invented the heliotrope, an instrument for marking positions in land surveys, and he worked with Wilhelm Weber on the measurement of the Earth's magnetic field. His work in electromagnetism earned him recognition in terms of the international unit of magnetic induction being named the *gauss*.

As his fame spread throughout the world, Gauss was the mathematician of choice when it came to complex mathematical questions. In his later years, he was criticized for dismissing the ideas of younger talented mathematicians and was accused of attempting to claim their ideas as his own.

Bernhard Riemann

The German mathematician Bernhard Riemann, like Gauss, was working on a type of non-Euclidean geometry termed *elliptic geometry*. He was also involved in work on a generalized theory of geometry. During his work, Riemann broke away from two- and three-dimensional geometry as being too limiting and began instead to think in terms of higher dimensions.

Riemann attended Gauss's lectures and was one of the lucky few to actually benefit from his patronage. Riemann's form of non-Euclidean geometry supposed that there are no such things as parallel lines and that the angles of a triangle do not add up to 180° . His advances in geometry and his novel concepts unified and generalized the various existing forms of geometry. He also generalized the concept of mathematical space, curves, and surfaces. At the age of 26, Riemann gave a lecture on the foundations of geometry, outlining his version of mathematics, which supposed that there are many different kinds of space. Hitherto, we had envisioned ourselves as inhabiting just one type of space, the flat Euclidean type of space. Riemann also put forth his one-dimensional complex manifolds, termed *Riemann surfaces*. These theories fundamentally changed how we see the world and paved the way for the development of higher dimensional geometry.

Riemann's metric left the limitations of two- and three-dimensional geometry behind, and even Bolyai and Lobachevsky's curved spaces, in favor of higher dimensional geometry. He extended the differential geometry of surfaces into n dimensions and devised a conception of a multidimensional space. This became known as *Riemannian space*, and it was this concept that allowed for the future development of the theory of relativity, which forms the basis of much of modern-day mathematics. Riemann was responsible for introducing the collection of numbers known as *tensors* into mathematics. These applied at every point in space and described to what extent space was curved or bent. For example, in four spatial dimensions, a group of 10 numbers is required at each point to describe the mathematical space's properties, no matter the level to which it is distorted.

Riemann is perhaps best known for his work on a function in the complex plane termed the

Riemann zeta function. This builds on the simpler zeta function created earlier by Euler. Riemann used this function to build a three-dimensional landscape and recognized that this theoretical landscape could be used to unlock the fundamental, longed-for solution to prime numbers. He noticed that the surface of his three-dimensional graph dipped to height zero at key places. This enabled him to demonstrate that the first 10 zeroes, for some unknown reason, appeared to line up in a straight line through the three-dimensional landscape of the zeta function. This became known as the *critical line* and the observation became known as the *Riemann hypothesis*. This theoretical leap took Riemann to the realization that these zeroes were connected in a completely unexpected manner to the way prime numbers are distributed. Riemann calculated that he could perhaps use this as a framework to correct Gauss's guesswork, in which he regarded the number of primes as numbers when counting higher and higher. Riemann's hypothesis, which remains unproven, purports that all the zeroes would theoretically be on a straight line and provides a strong indication that Gauss's approximations were accurate and that the primes are distributed over the universe of numbers in a balanced, beautiful, and regular way.

Riemann's hypothesis of the zeta function was published in 1859, but, unfortunately, many of his papers on the topic were destroyed in a fire after his early death, aged just 39. Today, the Riemann hypothesis is still one of mathematics' greatest unsolved questions, and a prize of over \$1 awaits the first person who can offer a final solution.

Boolean Algebra and Logic

In the mid-19th century, the British mathematician George Boole created a system of algebra, which is now known as *Boolean algebra* or *Boolean logic*. In his system, the only operators were *and* or *and not*, and these alone could be used to solve logical problems and mathematical functions. Boole also devised a binary system, which depended on just two objects: *on or off*; or *true or false*; or 0 or 1. In this system, Boolean algebra was famously born: $1 + 1 = 1$. Boolean algebra provided the basis for modern

mathematical logic, ultimately leading to the development of computer science.

Boole was one of the few mathematicians since Gottfried Wilhelm Leibniz (1646–1716) to seriously consider logic and its implications. Boole, unlike Leibniz, however, looked at logic as a discipline of mathematics rather than of philosophy. Unlike many other mathematicians at the time, Boole did not demonstrate his talent early in life. He was 34 before he published anything of note. He first began to see the possibilities of using algebra for solving logical problems by pointing to the deep analogy between the symbols of algebra and those of logic in terms of forms and syllogisms. He became determined to devise and develop a system of algebraic logic that would even go so far as to define and model the brain's function. He professed a profound confidence in logical reasoning, speculating a *calculus of reason* in the 1840s and 1850s.

Boole set out to find a way to encode logical arguments in a language that allowed them to be solved mathematically. His form of linguistic algebra, now termed Boolean algebra, involved three basic operations. These are *and*, *or*, and *not*; and Boole saw these as the only necessary operations required to perform comparisons of things and to carry out basic mathematical functions. The use of symbols and connectives enabled Boole to simplify logical expressions, for example, the algebraic identities of $(X \text{ or } Y) = (Y \text{ or } X)$, $\text{not}(\text{not } X) = X$, $\text{not}(X \text{ and } Y) = (\text{not } X) \text{ or } (\text{not } Y)$, and so on. He also devised a new approach based on a binary system, which involved processing just two objects: “yes–no,” “true–false,” “on–off,” and “zero–one.” If “true” is represented by 1 and “false” is represented by 0, then under the terms of Boolean algebra, it is possible for $1 + 1$ to be equal to 1 (where “+” is an alternative representation of “or”).

During Boole's lifetime, his ideas were largely ignored or criticized. It was not until the American philosopher, mathematician, and logician Charles Sanders Peirce (1839–1914) took them up and elaborated on them that they received the recognition they deserved, and this was several years after Boole's death in 1864. Then, more than 70 years later, Claude Shannon (1916–2001) made the connection between Boole's theories and their application to the processes and mechanisms of the real world. In fact, Boole's system is used nowadays in

the electromechanical relay circuits that underlie modern electronics and digital computers.

An Irish mathematician, William Rowan Hamilton (1805–1865), extended the concept of number and algebra further, in 1843 coming up with the theory of *quaternions*, a four-dimensional number system. This theory asserted that a quantity representing a three-dimensional rotation can be described by just an angle and a vector. Quaternions provided the first example of a noncommutative algebra, where $a \times b$ does not always equal $b \times a$, thus showing that several different consistent algebras may be derived by selecting alternative sets of axioms.

Hamilton's quaternions were later extended and developed by Arthur Cayley (1821–1895), who was also a pioneering mathematician in the area of modern group theory, higher dimensional geometry, matrix algebra, and the theory of invariants.

During the 19th century, mathematics became more abstract and complex; however, it also saw some mathematicians returning to their roots, with the emphasis on mathematical rigor. In the early part of the century, Bernard Bolzano (1781–1848) was one such mathematician, who put the focus on analysis and came up with the first pure analytical proof of the fundamental theorem of algebra and the intermediate value theorem. He also made early forays into the world of mathematical sets or collections of objects defined by a common property, for example, all numbers greater than 5.

Riemann and the French mathematician, engineer, and physicist Augustin-Louis Cauchy (1789–1857) rigorously reformulated calculus, which led to the development of mathematical analysis. This was a system of pure mathematics involved with the notion of limits. These could be limits to sequences or functions and with the theories of integration, infinite series, and differentiation. In 1845, Cauchy proved a theorem (known as *Cauchy's theorem*) that was a fundamental group theory. The German mathematician Carl Jacobi (1804–1851) made significant contributions to analysis too, as well as in the areas of determinants, matrices, and periodic functions.

Georg Cantor

In the latter part of the 19th century, Georg Cantor made a significant impression on mathematics.

The German mathematician's first papers were on number theory, but he was soon to turn his attention to calculus or analysis. He aimed to solve an ongoing problem on the uniqueness of the representation of a function by trigonometric series. What he remains best known for, however, is being the first mathematician to grasp the meaning of infinity and accord it a mathematical precision. Galileo had attempted to tackle the concept of infinity back in the 17th century along with the difficulties thrown up by comparatively different infinities. He managed to show that a one-to-one correspondence could be drawn between all the natural numbers and the squares of all the natural numbers to infinity. This suggested that there were as many square numbers as integers which goes against common sense since we intuitively know that there are many integers that are not squares. This concept became known as *Galileo's paradox*. Galileo also revealed that two concentric circles must both be made up from an infinite number of points, although the larger circle would seem to contain a larger number of points. Galileo eventually admitted defeat, concluding that concepts such as less, greater, and equal to could be applied only to finite sets of numbers rather than infinite sets per se. This was Cantor's challenge, and he first took it up by stating that if it were possible to add one and one, or 20 and 20, and so on, it ought to be possible to add infinity and infinity. He understood that it was possible to add and subtract infinities and that there existed another larger, then yet another larger infinity beyond the standard notion of infinity.

This idea of an *infinity of infinities* clearly had philosophical as well as mathematical implications, and the theory would change the approach to mathematics forever. Cantor's theory derives from his consideration of an infinite series of natural numbers (1, 2, 3, 4, etc.) and then an infinite series of multiples (15, 30, 45, etc.). He saw that while the multiples of 15 were a subset of the natural numbers, the two series could be paired, one-to-one. For example, 1 could be paired with 15, 2 with 30, and so on. This process is termed *bijection*, and it illustrates that both sets were in effect the same size because they had the same number of elements. This can clearly apply to other subsets of natural numbers, for example, the odd numbers 1, 3, 5, 7, and so on, or to squares 1,

4, 9, 16, and so on. It could even apply to sets of negative numbers and integers. Cantor found that he could even pair up all fractions or rational numbers with whole numbers, revealing that rational numbers possessed the same sort of infinity as natural numbers. This was out of line with the fact we intuitively feel there must be more fractions than whole numbers.

The difficulty lay in considering decimal numbers, which include irrational numbers such as π , e , and $\sqrt{2}$. He came up with some ingenious arguments, for example, the *diagonal argument*, to prove it was always possible to construct a new decimal number that was missing from the original list. This provided the evidence that the infinity of decimal numbers was bigger than the infinity of natural numbers. Cantor also managed to show that these numbers were *uncountable*, which meant they contained more elements than it would ever be possible to count. This is in opposition to rational numbers, which were technically *countable*. Cantor used the term *transfinite* to distinguish the levels of infinite numbers from an absolute infinity, which he equated with God. While the size of a finite set is simply a natural number stating the number of elements in the set, there needed to be a form of notation to describe the sizes of infinite sets.

Cantor's revolutionary theory on infinity heralded a new era in mathematics. It also led to the idea of the *continuum hypothesis*, whereby there can be other infinities, or even lots of infinities, between the infinity of whole numbers and the bigger infinity of decimal numbers. Cantor himself did not believe there was any such infinite set. The continuum hypothesis was, however, an ongoing puzzle for another century when it was taken up by Julia Robinson and Yuri Matiyasevich in the mid-20th century.

While Cantor's work on the concept of infinity was a landmark in mathematics, he also completed important work in set theory. This work has since become integral to modern-day mathematics throughout all the various branches that have grown up. The concept of a set had been implicit since the dawn of mathematics in Aristotle's day; however, it was limited to general finite sets. The infinite was not considered suitable for mathematics and was kept to a purely philosophical discussion. Cantor, however, succeeded in showing that there could in fact be infinite sets of

different sizes, just as there were finite sets. Some of these would be *countable* and some *uncountable*. During the latter part of the 19th century, Cantor worked on refining his set theory and produced definitions of *well-ordered sets* and *power sets*. This led to the introduction of his concept of ordinality and cardinality. What we now known as *Cantor's theorem* pronounces that

For any set A , the power set of A (set of all A 's subsets) has a cardinality which is greater than A .

This means the power set of a *countably* infinite set is uncountably infinite.

Although Cantor's set theory has become a part of today's mainstream mathematics, it was widely mistrusted by Cantor's peers. Some theologians saw his discussion of the infinite as an attack on their view of the nature of God. Others saw it as the willful destruction of the whole basis of mathematics. This included mathematician Henri Poincaré, who compared Cantor's set theory to a disease. There were some, however, who could see its potential, including David Hilbert, who declared Cantor's set theory to be a *paradise*.

As Cantor grew older, he succumbed to mental illness, which some viewed as a result of spending so much time contemplating such complex, abstract, and paradoxical concepts. He became obsessed with the notion that it was Francis Bacon who had written the Shakespearean plays and that Jesus was in fact the natural son of Joseph of Arimathea. He died alone in his room at the Halle sanatorium, leaving his life's project unfinished.

Henri Poincaré

Henri Poincaré was a leading light in the world of mathematics at the end of the 19th century and excelled in virtually all fields from geometry and algebra to analysis. He was a big believer in intuition and saw it as just as important as logic in the process of discovery. Poincaré is well known for his partial solution to a puzzle that had plagued the mathematicians Euler, Lagrange, and Laplace. This was termed the *three-body-problem*. Isaac Newton had shown that the paths of two planets in orbit around each other would stay stable, but the addition of even one more orbiting body would result in the involvement of up to 18 differing variables,

including position, velocity in either direction, and so on. This would make it mathematically too difficult to be able to predict or disprove a stable orbit.

Poincaré provided a solution to this vexing problem by setting out a series of approximations of the orbits. While this did not entirely solve the problem, it did enough to win him a generous prize from the King of Sweden in 1887.

In retrospect, Poincaré realized he actually had been mistaken. His simplifications did not imply a stable orbit, and in fact, just a slight deviation from his initial conditions would result in vastly different orbits. This realization, despite being born from error, resulted in a new theory now known as *chaos theory*, which is well known for being the theory which implies that the fluttering of a butterfly's wings could lead to a tornado on the other side of the planet. The theory was the first to indicate that there is a threshold for chaotic behavior. Poincaré's mistake, instead of diminishing his reputation, served to enhance it. He went on to develop the science of topology, first instigated by Leonhard Euler with his "Seven Bridges of Königsberg" problem. Topology is a form of geometry involving one-to-one correspondence of space, and it is also sometimes called *bendy geometry* since it implies that two shapes are the same if one can be morphed into the other without any cutting. Topology would state that a football and a banana are topologically equivalent. And so are a doughnut, which has a hole in the middle, and a teacup, with its handle. However, a doughnut and a football differ topologically because one cannot morph into the other. Poincaré produced a list of all possible two-dimensional topological surfaces. However, when it came to describing the three-dimensional universe, he came up with the *Poincaré conjecture*. This vitally important theory came to dominate mathematics for close to a century.

Poincaré also worked in theoretical physics, providing a presentation of the Lorentz transformations that formed an important step in the development of Einstein's theory of special relativity. He also contributed to areas such as optics, electricity, elasticity, quantum theory, and cosmology. Poincaré the engineer was also one of the last great mathematicians to adhere to a traditional view of mathematics, which felt that human intuition was as important as formalism and rigor. Often called the *last universalist*, he was one of the

last great mathematical all-rounders. The 20th century would see the rise of the specialist in mathematics, since the field had become so much more varied and complex.

Other Notable Mathematicians of the 19th Century

This entry has briefly outlined some of the mathematicians who defined the 19th century. There were many others who made significant contributions to mathematics during this time. One name immediately stands out, that of János Bolyai, an accomplished mathematician who had studied under Gauss. Bolyai was obsessed with Euclid's fifth postulate, which had been a standard geometrical principle for over 2,000 years. The principle stated that only one line can be drawn through a given point, so that the line lies parallel to a given line that does not contain the point. Additionally, its corollary is that the interior angles of a triangle amount to 180° or two right angles. Even through his obsession with the problem was starting to make him ill, Bolyai continued to pursue his quest, ultimately concluding that it was possible for there to be consistent geometries that did not require Euclid's parallel postulate. Bolyai's imaginary, "hyperbolic" geometry explained the geometry of curved spaces on saddle-shaped planes where the triangle's angles did not add up to 180° , and seemingly parallel lines were not in fact parallel.

Although we can visualize a flat surface and a surface with a positive curvature, for example, a sphere such as planet Earth, it is impossible to imagine a hyperbolic surface with a negative curvature, unless it is over a small area where it would resemble a saddle. The concept of a hyperbolic surface seemed to go against reality and was a radical departure from Euclid's geometry. Bolyai's treatise was published in 1832 and was obviously well regarded by Gauss who, having read it, tried to claim the idea as his own.

Independently of Bolyai in the Russian city of Kazan, Nikolai Ivanovich Lobachevsky also developed a theory of geometry which was non-Euclidean. Lobachevsky had also been working on other significant mathematical concepts including a method for approximating the roots of algebraic equations and the definition of a function in terms of the

correspondence of two sets of real numbers. Lobachevsky, like Bolyai, also died penniless, and in obscurity, Bolyai having succumbed to the mental illness he had earlier developed as a result of his mathematical obsession.

Meanwhile, in Britain, mathematics was undergoing somewhat of a resurgence. Earlier in the century, Charles Babbage, a mathematician, philosopher, inventor, and engineer, had designed a machine that could not only automatically perform computations based on a program of instructions stored on cards but also could compute logarithms and trigonometric functions. It was not until 100 years later that a working model of his machine was made and found to work perfectly. During the 19th century, the Englishman George Peacock is credited with inventing symbolic algebra, and he is also renowned for extending the scope of algebra beyond the ordinary number system. Recognition of the possible existence of nonarithmetical algebras was an important step toward future developments in abstract algebra.

The German mathematician and theoretical astronomer August Ferdinand Möbius (1790–1868) gave his name to several discoveries including the *Möbius strip*, the *Möbius configuration*, the *Möbius function*, and the *Möbius inversion formula*. Marius Sophus Lie was primarily responsible for the theory of continuous symmetry and its application to the geometric theory of differential equations. Nicolò Paganini discovered the second smallest pair of amicable numbers in 1866, something entirely overlooked by mathematicians even as great as Euler. Richard Dedekind defined concepts such as similar sets and infinite sets and devised a notion that is now known as the *Dedekind cut*, which showed that an irrational number divides the irrational numbers into two sets or classes. The upper set is strictly greater than all members of the lower set. This means that every location on the number line continuum contains either a rational or irrational number, and there are no gaps or empty locations. This theory is still used as a definition of real numbers. In 1881, John Venn introduced *Venn diagrams*, which remain one of the best-known and most-used tools in set theory.

In 1896, two proofs for the Prime Number Theorem were presented, by Jacques Hadamard and Charles de la Vallée Poussin. These proofs

were developed independently but both illustrated that the number of primes occurring up to any number x is asymptotic (tends toward) $\frac{x}{\log x}$.

Hermann Minkowski developed a system of number theory termed *geometry of numbers* at the end of the 19th century. This was a multidimensional geometrical method for solving number theory problems. Complex concepts such as lattice points, convex sets, and vector spaces formed part of the theory. In 1907, Minkowski discovered that Einstein's special theory of relativity was better explained in a four-dimensional space. This is often known as *Minkowski space-time*.

In 1879, the influential mathematician Gottlob Frege (1848–1925) produced the *Begriffsschrift* (*Concept-script*), which set the stage for a new field of logic, especially in its rigorous approach to the treatment of functions and variables. Frege's attempt to prove that mathematics is a product of logic involved him in devising techniques far beyond the traditional logic of Aristotle. He was the first to introduce the notion of variables into logical statements, along with *quantifiers*, *existentials*, and *universals*. Frege took Boole's propositional logic a stage further by extending it into *predicate logic*. His groundwork paved the way for the radical intellectual advances of Bertrand Russell and Giuseppe Peano.

Conclusion

The 19th century saw an explosion in applied mathematics as the industrial revolution gathered pace throughout Europe. The turbulent French Revolution (1789–1799) had been followed by the development of the École Polytechnique in Paris. There the finest mathematicians in the country developed their skills in mathematics. Many graduates from the polytechnic went on to excel in specialized forms of engineering in terms of the building of roads, mines, and creating artillery.

During the 19th century, many national mathematical societies became no more including the London Mathematical Society in 1865, the Société Mathématique de France in 1872, and the American Mathematical Society in 1888.

MATHEMATICS, RENAISSANCE

The triumph of the postulational form of thinking based on deductive reasoning and its symbolic representations had been the characteristic features of mathematics during the Renaissance—a period of incredible cultural and intellectual advancement based on the revival of classical learning, which spread all over Europe in the 14th, 15th, and 16th centuries. Mathematics during this time had two distinct trends—the rise in arithmetical–algebraic studies and the development of the theory of fluxions (flowing or changing quantity, as it was termed by Isaac Newton). The mode of expression had changed from a mere set of rules for field workers or students to postulations for analysts with proper deductions and justifications (composing proofs).

The invention of the printing press around 1450 made it possible for hitherto unfamiliar classical works to be available to the scholars of 15th-century Italy, the cradle of the Renaissance, more

than ever before. The initial thrust of the Latin translations of Arabic algebraic and arithmetical treatises obscured the Greek mathematical works for a long time. Explorations of the ancient Greek works at that time were difficult because few people read classical Greek, and the translated works required advanced training in mathematics. Later, as 17th-century mathematicians resorted more and more to the Greek literatures, after overcoming their initial handicaps, mathematical thinking attained new heights through the ingenious use of extensive and elaborate expositions of Greek arithmetic and geometry, thus far untried by Western scholars. The word *mathematics* itself has its origins in the Greek word *manthanein*, used by Pythagoras (c. 569–c. 475 B.C.E.) to denote someone with exceptional and wide learning. The word also carries a meaning of being alert, awake, wise, and inquisitive. Renaissance mathematics, with all its emphasis on logic and specificity, evolved not only out of the intellectual achievements of ancient Greek civilization but also from the contributions of Mesopotamian, Chinese, Indian, and Islamic civilizations. Historian of science Peter Dear proposed a two-phase model for the understanding of the evolution of early modern science. The first phase, the scientific renaissance of the 15th and 16th centuries, was a period of restoration of the knowledge of nature. This phase gradually paved the way for the second phase—the Scientific Revolution of the 17th century—when scholars shifted their attention from recovery of classical learning to the innovations of the modern paradigms.

The Renaissance and Greek Mathematics

The ancient Greek scholars were the pioneers in the scientific analysis of applied knowledge. They added the element of logical structure to the study of geometry, raising it above a mere practical science needed for such mundane things as land acquisition and distribution. The Greeks were distinctive for their individual excellences.

Thales (c. 624–c. 546 B.C.E.), for example, is often considered as the first mathematician to whom several individual results are ascribed. He is known for his deductive methodology. Thales is also remembered for the first truly mathematical demonstration of the postulations, pioneering the

general way of understanding the geometrical (mathematical) truths that became the foundation of Renaissance mathematics. Thales's approach was more logical and comprehensive than the existing practice of formulating mere algorithmic statements or instructions. Pythagoras (c. 569–c. 475 B.C.E.) was rather a mystic and aristocratic figure with a scientific mind. The terms *philosophy* (“love of wisdom”) and *mathematics* (“that which is learned”) are known to have been coined by him. Pythagoras and his secret brotherhood demonstrated several theorems and constructions of geometry. The extant works on conic sections by Apollonius (c. 262–c. 190 B.C.E.) prepared the way for the astronomical inventions of the Scientific Revolution almost two millennia later. A summation of the years of Greek practices, thoughts, and improvements in mathematical knowledge can be seen in the *Elements* of Euclid (c. 300 B.C.E.). All the harmonies between the theories and realizations of arithmetic and geometry were upset, however by some problems posed by Zeno (c. 490–c. 430 B.C.E.) involving the infinite and the infinitesimal. In attempts to set right the instabilities that Zeno had rendered, Archimedes (c. 287–c. 212 B.C.E.) held up the exhaustion method that avoided the pitfalls of infinitesimal by simply discarding them. He was exceptionally bold among the Greeks in handling questions of infinity and the infinitesimal. The sophistication attained by the ancient Greeks was far beyond the reach of later generations of European mathematicians until the 17th century. The Greek scholars, however, made few significant advances except in geometry and trigonometry. This shortfall is sometimes ascribed to intellectual obstacles between Greek geometry, with its focus on whole numbers, and the roots of algebra. From its origins in ancient Egypt and Babylonia, however, algebra continued to develop in Asia, and this allowed Indian and Arabic scholars to act as an intellectual bridge between medieval and modern mathematical studies, riding upon the political wave of the Islamic invasion of the West.

Influences of the Islamic Tradition

The most significant historical development affecting Renaissance mathematics was the spread of Islam. Both Muslim and non-Muslim medieval scholars, living under Islamic rule, played a crucial

role by transmitting the Greek, Hindu, Chinese, and other pre-Islamic fruits of knowledge to Western world. It all started under the caliphate of al-Mamun (786–833), who set up the “House of Wisdom” in Baghdad. The initial stress was on the translations of all the important literatures collected from Persia, Greece, China, and India through trade connections and political treaties with the Roman Empire. Soon the Arabian scholars started analyzing and interpreting those texts with profound insights that opened new horizons in the history of mathematical thought.

Mohammed ibn Musa al-Khwarizmi (780–850), a noted scholar of Baghdad, started translating the Indian texts. His first book was an exposition of the Hindu scheme of numeration, which later enormously influenced Renaissance mathematicians. This scheme later came to be known after him as *algorism* or *algorithm*. Any given rule or procedure of operation is now called an algorithm. Perhaps, the most important work of al-Khwarizmi was *Al-kitab al-mukhtasar fi hisab al-jabr wa'l muqabala* (*The Compendious Book on Calculation by Completion and Balancing*), which gave a straightforward exposition of the solution of equations, especially of the second degree. *Al-jabr* contained rules for the operations on binomial expressions and the rules governing the negative numbers, though Khwarizmi rejected the negative roots as solutions. The deductive way of thinking and the structurally comprehensive mode of expressions with a distinct beginning and a precise conclusion were the features of the writings of the Arabian scholars that would later influence the theoretical structures of Renaissance mathematics. The rhetoric form of expression of the Arabian scholars, however, did not attract the Renaissance scholars of the West. The Arabic mathematical works were ramified in four major directions, all of which were ultimately formalized into a logically connected abstract mathematical schema emphasizing the postulational form of thinking, deductive reasoning, and symbolic expression in the following centuries. These were:

Numeration—Based on the Indian principle of positions and Greek or Roman form of numerals.

Algebra—Derived from the neighboring civilizations of Greece, Babylonia, and India but transformed into a new systematic form.

Geometry—Derived from the classical Greek postulational formulations with added generalizations and simplification of ideas.

Trigonometry—Developed from the Indian tables of sines with newly added functions and formulas motivated by the Greek geometry of chords.

The Scientific Renaissance

The scholar whose life and works can well represent the period of transition from medieval mathematics to the modern was Johann Muller (1436–1476) of Königsberg, Germany, who was popularly known as Regiomontanus. Regiomontanus graduated from the University of Vienna in 1457 and was appointed as a faculty member, whence he collaborated with his teacher Georg von Peurbach (1423–1469). Regiomontanus accompanied him to Rome to assist in translating Ptolemy's *Almagest*, commissioned by Cardinal Bessarion, which was ultimately bequeathed upon him when Peurbach died within a year. Bessarion was a scholar of mathematics and a native Greek speaker who owned the largest library in Europe. Regiomontanus learned Greek from Bessarion. He lectured in Padua and traveled around northern Italy with Bessarion, where he came in contact with Italian scholars and gained access to the major European libraries. Regiomontanus returned to Germany and settled in Nuremberg, where he wrote his major works under the patronage of a rich merchant. He set up the first scientific printing press, an astronomical observatory, and a small workshop for manufacturing astronomical instruments. Regiomontanus first printed a prospectus to announce his plan to print the translated versions of some important mathematical, astronomical, and geographical works. Then, he started his venture with printing the astronomical textbook *Theoricae Novae Planetarum* (*New Theories of the Planet*) by his teacher Georg Peurbach. Regiomontanus translated the works of Archimedes, Apollonius, Hero of Alexandria, Ptolemy, and Diophantus and made their printed versions available to the general readers. He started working on calendars and built an astrolabe. Regiomontanus also built a sundial for Pope Paul II.

With an objective to provide a systematic trigonometric account to support astronomical studies,

Regiomontanus wrote *de Triangulis Omnimodis* (*On Triangles*). In this treatise of five books, Regiomontanus followed the form of Euclid's writing. The first book included definitions of quantities, ratios, equality, triangles, circles, and other forms, as well as the axioms and theorems he used. The second book covered the solutions of triangles. In the remaining books, he focused on spherical trigonometry in order to strengthen the study of astronomy. These works lack the use of the tangent function, already defined by Nasir Eddin al-Tusi (1201–1274) and the use of fractional decimal expressions, which were to be adopted in a decade's time. His work *Algorithmus Demonstratus* was the first to employ symbolic algebra.

Regiomontanus wrote *Scripta* to describe all the astronomical instruments he collected and/or invented. He used one of them (Jacob's staff) to predict the appearances of a comet for the next 210 years, which was later identified as Halley's comet. He predicted lunar eclipses accurately and used lunar distances to calculate longitudes at sea. This method was also adopted by Christopher Columbus and Amerigo Vespucci in their exploratory voyages.

While working with triangles, Regiomontanus used the algorithmic methods devised by the Arabian algebraists to solve the roots of a quadratic equation of known coefficients in terms of sides of a triangle. This was strikingly different from the ancient Greek works. But owing to the rhetorical form of his expression and his premature death, his successors in Europe had to suffer a delay in the incorporating Arabic methods into the algebra of the ancient Greeks.

The form of mathematical studies of the Renaissance would exhibit features similar to those of the works of Regiomontanus. The explorations of ancient Greek works, the practical examinations of facts and their incorporations in framing the results, scientific collaborations, and publications of the findings to reach out to wider academic circle—all were landmarks in the trajectory of the history of the Renaissance mathematics.

Arithmetic and Algebraic Studies

The best-known exposition of 15th-century Europe was *Summa de Arithmetica, Geometrica, and Proportioni et Proportionalita* of the Italian

mathematician Luca Pacioli (1445–1514). In this book, one can find the first use of the notations p (for +) and m (for –) and the use of the term *cosa* for the unknown, which were echoed throughout Europe in the coming years. The work was a summary of the mathematical knowledge of the time and demonstrated no originality as such, but it still became famous for the illustrious figures drawn in it by Leonardo da Vinci; for the use of algebraic notations instead of rhetorical expressions; and for being the first book to deal with double-entry bookkeeping, games of chance, the golden ratio, rule of 72, and many such things that were to appear much later in the time line of the history of mathematics. Although Pacioli wrongly conjectured, however, that cubic equations cannot be solved algebraically, his work stimulated much thought about the topic.

Scipione de Ferro (1465–1526), a lecturer at the University of Bologna, solved a kind of reduced cubic equation and passed it on to his student Floridus. The University of Bologna at that time was famous throughout Italy for its mathematical competitions. In an effort to win over Floridus in such a competition of solving cubic equations, Niccolo Fontana “Tartaglia” (1500–1557) found solutions to all types of cubic equations, which were eventually published by Heironimo Cardano (1501–1576) in his *Ars magna* and known all over as his (Cardano’s) method of solution of cubics. Lodovico Ferrari (1522–1565), a student of Cardano, influenced by the methods of Tartaglia, worked on the methods of solutions of quartic equations. *Ars Magna* presents the details of solving cubic and quartic equations without any acknowledgment to either of Tartaglia or Ferrari. In attempts of claiming the originality of work, perhaps Tartaglia, Ferrari, and Cardano exhibited the first calculations involving complex numbers (though without much understanding). The controversial character Cardano was a prolific writer and a physician who gained the fame of the ablest algebraist of his time.

Rafael Bombelli (1526–1572), an Italian hydraulic engineer, was keenly interested in algebra. He followed the works of Ferrari, Tartaglia, and Cardan. Bombelli felt that after *Ars Magna*, the learned world needed a careful exposition of algebra, and he wrote *Algebra*. In this book, Bombelli solved many geometric problems algebraically, in a way

similar to that of Regiomontanus, with elaborate geometric illustrations. He designed symbols for the radicals and for the powers of unknown quantities, thereby taking algebra a step closer to modern symbolic representations. Bombelli’s greatest contribution was the identification of conjugates of imaginary numbers and the rules of addition and multiplication of the imaginary numbers. Bombelli later translated a part of Diophantus’s *Arithmetica* and solved many problems, duly acknowledging Diophantus while revising his *Algebra*.

With the availability of the Latin translations of Al-Khwarizmi’s *Algebra*, Arabian algorithm and algebra spread across Europe, and what was called *cosic art* (the study of the unknown) became more and more popular among scholars. In Germany, for example, Johann Widman (1462–1498) published *Behende und hübsche Rechnung auff allen Kauffmanschafften* using the notations of + and – for the first time on print. Rechenmeister Adam Riese (1492–1559) wrote *Die Coss* influenced by the works of Al-Khwarizmi, in which he first replaced the Roman numerals by the Hindu-Arabic numerals. Christoph Rudolff (ca. 1500–ca. 1545) of Vienna, in his book *Coss*, made use of decimal fractions, as well as the modern symbol for roots. But *Arithmetica Integra* of Michael Stifel (ca. 1487–1567) was the most important of all of the 16th-century German algebras. It is outstanding for its treatment of negative numbers, radicals, and powers. In this book, Stifel proposed the use of a single letter to signify the unknown and repeating the letter for higher powers of the unknown. He confidently used negative powers of numbers as well.

Robert Recorde (1510–1558) was the only mathematician of any stature seen in England over a span of almost two and half centuries. He wrote several textbooks to popularize the study of mathematics in his country. He, like Cardano, had a mathematics degree as well as a medical degree and would alternate between the two occupations. His publications *The Grounde of Artes*, *The Pathwaie to Knowledge*, *The Castle of Knowledge*, and *The Whetstone of Witte*, although not outstanding in content, were popular in the absence of other books in the vernacular. The importance of the last book, *The Whetstone of Witte*, lies in the introduction of the = sign. Recorde usually wrote in the medieval question-and-answer style, but the

Pathwaie was different. It was actually an abridged version of Euclid's *Elements*, in which Recorde tried to replace many of the Latin terms by his own verses. But for reasons that remain unexplained, these were not accepted by any successive writers.

Geometry

The 14th and 15th centuries did not witness much advancement in geometry as such. Instead, the geometric models provided the base for developing many important works in art and architecture during the Renaissance. The only remarkable representative in the study of geometry during the Renaissance was Johannes Werner (1468–1522). The work of Werner comprised 22 books entitled *Elements of Conics*. Although it was by no means comparable with the *Conics* of Apollonius (c. 262–c. 190 B.C.E.), it was engaged with the problem of duplicating of cube with a unique and ingenious method quite different from that of Apollonius. Geometrical knowledge was very creatively used by Renaissance painters, sculptors, and architects. It was in this period that a highly realistic linear perspective was developed. Artist Giotto di Bondone (1267–1337) was credited with the introduction of perspective in art. Later Leonardo da Vinci (1442–1519) and his contemporaries included in their works the ideas of ground plane, picture plane, vanishing point, and so forth, and thereby injected the elements of geometric logic to various art forms.

Astronomy and Trigonometry

Astronomy and trigonometry had been important branches of mathematical studies since antiquity. The Renaissance period saw them attain the full bloom in the hands of the Polish astronomer and mathematician Nicholas Copernicus (1473–1543), who gave the revolutionary heliocentric model in *De Revolutionibus Orbium Coelestium*, published in the year he died. Georg Joachim Rheticus (1514–1576) worked thoroughly on Copernican astronomy and wrote explanatory commentaries on his propositions. He also took trigonometry to its present form by writing an elaborate treatise entitled *Opus Palatinum de Triangulis* on the trigonometric functions. Rheticus discarded the forms of the trigonometric functions in terms of

the arcs of a circle and introduced the current definitions of the six trigonometric functions using the sides of a right triangle. He calculated elaborate tables for intervals of 10° in angles. He, however, failed to use the concept of decimal fractions introduced by the Persian scholar Jamshid al Kashi (c. 1380–1429) in the 15th century and used very large numbers for sides of triangles instead. Although essentially the advancement made by Copernicus and his disciple Rheticus marked the beginning of the Scientific Revolution, but as always, revolutions do not wait for a category.

The Scientific Revolution

The period from the publication of *De Revolutionibus Orbium Coelestium* in 1543 by Copernicus to the publication of *Principia* in 1687 by Isaac Newton marks the era called the Scientific Revolution. This revolution changed man's belief and the thought process. The leading personalities of this era tried to explain the relationship of humans with nature from every possible epistemological point of view. From the four qualities that, according to Aristotle, constitute the universe to the existence of the atoms composing everything in the universe, as proposed by Newton, was a great leap in humanity's conceptions of existence. Thinkers of the era overturned the authority of the church, of the physical laws of Aristotle, of the geocentric views of Ptolemy, and of the anatomical and physiological conclusions of the Roman physician Galen that had overshadowed human thought since the beginning of the Common Era.

By the end of the 15th century C.E., there were at least 50 universities across Europe, including the universities founded in the 13th century in Paris, Bologna, Oxford, and Cambridge. Education took an important role in training the youth not only for an occupation but also for a better life. Educationalists included mathematics in all the courses after the reforms of the medieval curricula in the universities. They advocated for the need of mathematics in administration, trade, art, architecture, engineering, and all branches of natural sciences. Some even advocated the need of mathematical studies for spiritual uplift in consonance with the ancient Pythagorean philosophy. Some educationists even integrated the poor into the education

system for the general improvement of society. As a result of all this, mathematics took an important role in the reconstruction of the social world. Many schools were opened, and a new occupation was generated—the *math tutor*—who bore the responsibility of spreading general awareness of mathematics among the masses. Thus, the common people gained access to the knowledge of mathematics as they had never done before.

Astronomy and Geometry

As noted earlier, the introduction of the heliocentric model had revolutionized astronomy and changed the society for good. Galileo Galilei (1564–1642) made fundamental contributions. He claimed that the motion of the planets was actually the motion of falling bodies. His discoveries, pioneering the use of telescope, paved way for the acceptance of the heliocentric model of Copernicus. This simultaneously established experimentation as an important aspect of applied mathematics. Johannes Kepler (1571–1630) took the subject even further by providing laws of planetary motion, which laid the foundation for Newton to establish his universal law of gravitation. In his *Astronomia Nova*, Kepler gave the first two laws of planetary motions.

Kepler also studied the works of Apollonius in detail and came up with the principle of continuity for conics, in which he showed how necessarily moving the focus (possibly to infinity) one can obtain one conic from the other. Kepler also dealt with the problem of the infinitely small. He estimated areas by filling them up with very small triangles, thereby exercising a very preliminary type of integral calculus. The idea of the “points at infinity” as speculated by Kepler was devised formally by Girard Desargues (1591–1661) as the point where the parallel lines intersect. Desargues introduced the perspective theorem and in course developed the subject called *projective geometry*. The ease with 17th-century mathematicians dealt with the concepts of infinity and the infinitesimal completely revolutionized mathematics.

René Descartes (1596–1650) was the first person to associate geometric shapes to algebraic equations in a two-dimensional system (hence named after him as the Cartesian coordinate system) bridging algebra and geometry. Thereby, Descartes constructed the

last segment of the road to infinitesimal calculus. His work in *La Geometrie* makes the first step toward a theory of invariants.

Number Theory

Pierre de Fermat (1601–1665) influenced by *Arithmetica* of Diophantus started working on numbers and their patterns and invented number theory almost single-handedly. He went on to formulate conjectures on the properties of numbers and proving them mostly in communications with friends. He outlined the proofs of some of his conjectures, which his contemporaries often found inadequate in constructing a proof. But later, much of his work was derived from his outlines. The most celebrated conjecture of Fermat was known as the *last theorem*, which remained unsolved for more than 350 years and got tagged to several mathematical academy prizes offered in return for a proof. The theorem finally was proved in 1995, making it the most difficult problem in mathematics to date.

Through communication and collaboration with Fermat, his French contemporary Blaise Pascal (1623–1662) fathered the mathematical theory of probability, which was initiated by Cardano in his expositions on games of chance. Pascal wrote a significant treatise on projective geometry. However, the name of Pascal is attached more popularly to the triangular array of binomial coefficients. Pascal did not construct it rather he derived it from the ancient Greek works. He was the one to provide a proof by defining the recursive relation of the numbers and exhibit the interesting patterns in the triangle, which had come up in many previous works since antiquity.

The Renaissance Function: Logarithm

While working with sequences, the Scottish mathematician John Napier (1550–1617) was once told that the astronomers were overburdened by voluminous calculations in course of their work. This encouraged him to devise some methods of reducing the burden of performing large multiplications and divisions by large numbers. He worked hard and published the *Mirifici Logarithmorum Canonis Descriptio* (*A Description of the Marvellous Rule of Logarithms*) in 1614. The basic idea

behind his invention of logarithms was simplification of large computations. In his work, Napier demonstrated a very interesting kinematic model to explain the formation of the arithmetic and geometric sequences used in the construction of his tables of logarithms. This shows how well equipped the 16th-century mathematicians were to compare arithmetic and geometric sequences and exemplify the result through an example of nonuniform motion. The work of Napier would greatly facilitate the huge calculations of the future astronomers and physicists. Laplace, commenting on the works of Napier two centuries later, said, “By halving the labor of the astronomers he (Napier) doubled their lifetimes.”

Napier built his tables numerically and not geometrically, as the name logarithm (*logos* in Greek means ratios and *arithmos* means numbers) suggests. But he was oblivious of the idea of base, or of the choice of base, which would simplify his calculations further. Upon long conferences with Napier, Henry Briggs (1561–1630), a London mathematics professor, convinced Napier of the use of base 10 instead of his base *e*. Briggs then published his work in 1624 in *Arithmetica Logarithmica* with elaborate logarithm tables of 30,000 natural numbers to 14 decimal places. This function became an indispensable tool of calculations for the next 300 years.

The Renaissance Idea: The Infinitesimal and the Theory of Fluxions

A modest confession of Isaac Newton (1642–1727) was “If I have seen further, it is by standing on the shoulders of giants.” Mastering the geometric ideas of the Greek and the algebraic ideas of Descartes, Newton put forward his theory (published posthumously in *Methodus Fluxionum et Serierum Infinitarum*) of the *fluents* (the variable), the *moments of fluxions* (infinitesimally small increments), and the *fluxions* (flow of the variable). He considered derivatives primarily as velocities and integration as the sum of an infinite series. However, his hesitation to publish the work gave rise to public and private disputes regarding the priority of the discovery of calculus. This was because of Gottfried Wilhelm Leibniz (1646–1716), who published his ideas of tangency, maxima, minima, and estimates of areas in 1684 in the *Acta Eruditorum* (one of

the earliest monthly scientific journals), which brought the theory of calculus to the fore before Newton could do so. Leibniz had studied the works of Descartes and Pascal and was in personal contact with the Dutch mathematician Christiaan Huygens. In his publications, Leibniz gave details of the rules of differentiation and some of the rules of integration. Later, he was joined by the Bernoulli brothers, Jacob and Johann, and they together put forward what we see today as undergraduate calculus. Most of the calculus notations we use today were designed by Leibniz. Both Newton and Leibniz failed, however, to clear the idea of the infinitesimal (the moment of fluxion of Newton and point of tangency of Leibniz), which was attacked heavily by Bishop George Berkeley (1685–1753) calling them as “ghosts of departed quantities.” This inspired further constructive work, and calculus then became invaluable in almost all fields of scientific endeavor.

During the 17th century, several mathematical academies and societies were formed under royal patronage in different parts of Europe. Parallel to the mathematical studies and teachings at the universities, these bodies promoted further research by providing financial assistance, offering prizes and awards, and helping the scholars to publish their research findings in scientific journals all over Europe. These mathematical societies became the conglomerate of the mathematicians collaborating with each other. Enthusiasts like Marin Mersenne and John Collins acted as correspondents, keeping their contemporaries informed about the challenges and open problems of mathematics and inviting their solutions. It is through the exchanges and collaborations of mathematical activities under the supervision of the chosen stalwarts heading such societies that the scholars entered into healthy competitions, taking the subject to soaring heights. The Royal Society of London, French Academy of Science, Italian Royal Society, Royal Academy of Berlin, Royal Academy of Paris, and St. Petersburg Academy all played vital roles in the spreading a strong research culture in mathematics.

MATHEMATICS, 20TH CENTURY

The 20th century saw the trends of the 19th century continue in terms of the increasing abstraction and generalization of mathematics. The notion of axioms as *self-evident* truths became obsolete as an emphasis on logical concepts such as completeness and consistency took hold. During the 19th century, mathematics also became a growing domain for professional employment, with thousands of new jobs created in teaching and in industry. Hundreds of new fields of mathematics came into play—such specialized areas of study as knot theory, group theory, topology, functional analysis, sheaf theory, singularity theory, graph theory, and others. This entry describes the major developments of the period, focusing on the conceptual breakthroughs and notable achievements of

prominent mathematicians whose work has served to advance the discipline.

G. H. Hardy and Srinivasa Ramanujan

G. H. Hardy (1877–1947) was, along with his protégé Srinivasa Ramanujan (1887–1920), a leading light of early 20th-century mathematics. Hardy's aim was to solve the problems left behind by the previous century, including the Riemann hypothesis. A somewhat eccentric figure, Hardy is probably best known for his work on number theory and mathematical analysis. As a prodigy from a young age, he spent the best part of his academic career at Cambridge University. He is often recognized for reforming British mathematics at the start of the 20th century by instilling a rigor more often associated with that of continental mathematics. Hardy greatly admired German and Swiss mathematicians and was determined to bring to Britain the new tradition of pure, as opposed to applied, mathematics, a type of mathematics which had flourished in Britain since the times of Isaac Newton. He was proud of the fact he had never contributed to anything military or commercial, and he was outspokenly pacifist in his views.

Shortly before the outbreak of the First World War, Hardy claimed to have solved the Riemann hypothesis. What in fact he had accomplished was proof that there were infinitely more zeroes on Riemann's *critical line*. He did not, however, succeed in proving that other zeroes which weren't on *the line* existed—or indeed, that other zeroes elsewhere could not exist.

Hardy famously mentored the talented mathematician Srinivasa Ramanujan, who was originally from Madras in India. Ramanujan wrote to Hardy claiming that he had discovered a formula for calculating the number of primes up to 100 million, a formula that had virtually no errors. Ramanujan was obsessed with proving Riemann's results despite the fact he had had almost no formal mathematical tuition and in fact claimed that most of his ideas came to him in dreams. Hardy, unlike his peers, recognized Ramanujan's genius and invited him to Cambridge University, where he was to befriend and mentor Ramanujan for many years. Hardy and Ramanujan were to collaborate on many mathematical puzzles, although the solution

to the Riemann hypothesis eluded them for their lifetimes. Ramanujan was a prolific mathematician and is believed to have proved or conjectured over 3,000 theorems, equations, and identities, including the partition function, along with its mock theta functions, and the properties of highly composite numbers. He was also involved in work on modular forms, prime number theory, gamma functions, and hypergeometric series problems. Ramanujan was also recognized for his identification of numerous efficient and rapidly converging infinite series, used to calculate the value of π . Some of these series could compute eight decimal places of π with each term in the series. Ramanujan's series are today the basis of the fastest algorithms used by computers, which can now compute to about 5 trillion decimal places.

Ramanujan died at just 32 after falling into a depression and becoming seriously ill. After his death, certain of Ramanujan's other discoveries including the Ramanujan prime and theta function have paved the way for further research, finding practical applications in such varied fields as string theory and crystallography. Hardy, however, lived for a further 27 years, his greatest contribution to mathematics being, in his words, *finding Ramanujan*.

In a related development, the German mathematician Johan Gustav Hermes managed in 1904 to complete construction of a regular polygon with 65,537 sides, using just a compass and straight-edge. This accomplishment took him 10 years.

The early 19th century also heralded the rise of mathematical logic, which built on the earlier work of Gottlob Frege. Mathematicians Giuseppe Peano, David Hilbert, L. E. J. Brouwer, Bertrand Russell, and Alfred North Whitehead took over the mantle, with one of the century's most influential works, *Principia Mathematica*, a joint publication by Russell and Whitehead.

David Hilbert

Right at the beginning of the century, German mathematician David Hilbert (1862–1943) gave an address at the Sorbonne, Paris, in which he set out what were in his view the 23 most important unsolved mathematical problems of the times. *Hilbert's problems*, as they became known, set the agenda for many decades to come. Of the 23

problems, 10 have thus far been solved, seven partially solved, and two, the ever-perplexing Riemann hypothesis and the Kronecker–Weber abelian theorem, still unresolved. Four of the problems are considered to be too vaguely formulated for them to be embarked on.

Hilbert, like many other mathematicians before him, had attended Göttingen University and spent much of his working life there. Considered an *out of the box* thinker, Hilbert went on to have numerous mathematical terms named after him, for example, *Hilbert space*, *Hilbert curves*, and *Hilbert inequality*. He also devised some important theorems, eventually becoming one of the best-known mathematicians of the 20th century. In his younger days, Hilbert had worked on number theory and abstract algebra, and then, he changed direction to work on integral equations. His work on integral equations helped to reinvent the field and led to what was known as his *finiteness theorem*. Hilbert managed to prove that, while there were an infinite number of possible equations, it was nonetheless possible to split them into a finite number of *kinds* of equations. These could then be used to build all other equations. Although Hilbert himself was unable to build these equations, he could simply prove the necessity of their existence. This type of proof is referred to as an *existence proof* rather than a *constructive proof*. Critics at that time tended to dismiss Hilbert's proof as having no practical basis, but his proof was to set the tone for a brand-new style of abstract mathematics. The use of existence proofs rather than constructive proofs became an implicit aspect of his development of Hilbert space. This was a generalized form of Euclidean space, an extension of the use of vector algebra and calculus to spaces possessing a finite or possibly even infinite number of dimensions. This progression of space theory formed the basis of much of the contributions to mathematical physics for many years to come. Some consider it to be one of the best explanations of quantum mechanics in existence.

When giving his famous enunciation of the problems of mathematics, Hilbert was convinced that solutions would be found, even postulating that there are no mathematical problems that cannot be solved. "We must know! We will know!" was famously inscribed on his tombstone as

evidence of his conviction. His belief that mathematics should be put on logical foundations where there were no limits was behind his unshakeable optimism. For Hilbert, the basis of mathematics was not in logic per se, but in a simpler system of prelogical symbols. These could be amassed to form strings and axioms, then a set of rules, or *rules of inference*, could be applied to them. He devoted much time to finding a consistent, complete set of axioms for the whole field of mathematics (this was *Hilbert's program*). By the start of the 20th century, Hilbert had set out an entirely new formal set of geometrical axioms, which became known as *Hilbert's axioms*, as opposed to the traditional axioms devised by Euclid.

This work, however, was definitively stopped in its tracks by Kurt Gödel's theory of incompleteness in the 1930s. The desire to understand Gödel's work however furthered a new objective, that of developing recursion theory and mathematical logic as an autonomous discipline, something that was later to provide a foundation for theoretical computer science.

Hilbert could only look on in horror at the ensuing Nazi repression of his Jewish mathematician friends and colleagues in Germany during the 1930s as well as the systematic destruction of what was the one of the foremost mathematical centers in human history. At the time of his death in 1943, Hilbert's work was little known, and he died in obscurity.

Bertrand Russell and Alfred North Whitehead

Two other towering figures in the 20th century mathematics were Bertrand Russell and Alfred North Whitehead, mentioned earlier in this entry. Both were mathematicians, philosophers, and logicians, who disparaged *continental idealism*. Both made significant contributions to the fields of mathematics, logic, and set theory.

Russell is considered one of the chief founders of analytic philosophy, while his mathematics was heavily influenced by the set theory and logic of Gottlob Frege—Frege having developed the earlier work of Georg Cantor. Russell is well known for his *paradox* of a set containing all of the sets that are not members of themselves. This indicated that Frege's *naive* set theory entailed contradictions.

The paradox is often illustrated using this example: "If a barber shaves only and all the men in the village who do not shave themselves, does he shave himself?" Russell's paradox appeared to put the whole of mathematics on a shaky footing with the implication that perhaps not even mathematics could be relied upon to provide us with the truth in absolute terms. Russell's work certainly shook Frege's confidence, something he was honest enough to admit in an appendix to his *Basic Laws of Arithmetic*.

But it was the *Principia Mathematica* that was to seal Russell's fame, a work published in three volumes between 1910 and 1913. The first he cowrote with Whitehead, but the latter two were written almost entirely by Russell alone. The *Principia* was an attempt to derive all mathematics from a set of purely logical axioms without running into the kinds of paradoxes that plagued Frege's work on set theory. Russell succeeded in this by devising a system of *types*, whereby objects of a certain type are built exclusively from objects of types which precede them, lower down the hierarchy. This ensures that the problem of loops is avoided. Since each set of elements is of a different type from each of its elements, we cannot view the system in terms of *sets of sets* and we thereby avoid the usual paradoxes. The *Principia* also required the addition of three further axioms, which were true not simply because of the laws of logic. These were, first, the *axiom of infinity* to guarantee the existence of at least one infinite set—the set of all natural numbers; second, the *axiom of choice* to ensure that given any collection of *bins* containing at least one object, it is possible to select exactly one object from each bin. This must be possible even if there are an infinite number of bins and although there is no set *rule* about which object to choose from each bin. The third axiom was Russell's *axiom of reducibility*, which would ensure that propositional truth functions can be expressed by predicative truth functions.

The extensive scope of the *Principia* is illustrated by the fact that it takes 360 pages to prove that $1 + 1 = 2$. The book is still considered one of the most important works in the history of mathematics, on a par with Aristotle's *Organon*. In the 1930s, Gödel's incompleteness theorem struck again, however, proving that the *Principia's* contents were neither consistent nor complete.

Kurt Gödel

Kurt Gödel (1906–1978) was an Austrian mathematician, who put intense constraints on what could and could not be proven. He effectively turned mathematics on its head with his incompleteness theorems. They seemed to prove what had hitherto been unthinkable—that there were solutions to mathematical problems that could not be proven—ever. Gödel studied number theory at the University of Vienna but became fascinated by mathematical logic, and it was to this he then devoted his entire career. Early in his life, he, like Hilbert before him, was optimistic that mathematics could be made whole and unproblematic. He became part of the famous Vienna circle of intellectuals during the First World War and discussed philosophical ideas with logical positivists such as Rudolf Carnap, who rejected metaphysics as empty and meaningless, in favor of a codified basis for the language of science. Gödel was influenced by this positivistic outlook although he himself did not become a logical positivist. Instead, he turned his attention to finding a logical foundation for all mathematics. What he discovered, however, was that there was no such thing.

In recognition of Hilbert's optimism that there could be a logical basis for mathematics, Gödel first drew up his completeness theorem. This illustrated that all the valid statements in Frege's *first-order logic* can be proven from a set of basic axioms. When it came to extending that logic to include arithmetic, however, the difficulties appeared. Gödel's incompleteness theorem (or theorems, since there were actually two) showed that in any mathematical system at least that powerful, there would be statements that, although they might be true, could never be proven. Gödel had used the plain language assertion "this statement cannot be proved," which was an updated version of the *liar paradox*, an assertion which of itself must be true or false. If the statement is false, it shows that the statement can be proved, thereby suggesting that it is in fact true—and thus generating a contradiction.

In order for Gödel to apply this deduction to mathematics, he had to convert the statement into a formal language or pure statement of arithmetic. He did this by the use of a code based

on prime numbers, in which strings of prime numbers take over the role of natural numbers, rules of grammar, operators, and all other aspects of formal language. The mathematical statement that ensued appeared just like its natural language equivalent as true, but impossible to prove.

The incompleteness theorem caused a crisis in the world of mathematics. To be able to state something as true but be unable to prove, it was a mathematician's worst nightmare. Gödel thereby stopped many mathematicians in their tracks, including Russell and Hilbert. He had provided proof that any system of numbers or logic dreamt up by a mathematician would fail to succeed in coming up with a full set of provable assumptions.

Gödel, like Cantor before him, also applied himself to the problem of the *continuum hypothesis*. He made an important development in resolving it by proving that the axiom of choice is independent from finite type theory. Unfortunately, Gödel, like Cantor, also suffered from a form of mental deterioration and underwent a series of mental breakdowns. He was also forced to witness the destruction of his mathematical community at the hands of the Nazis, which caused him to flee to the United States. At Princeton University, he befriended Albert Einstein and made contributions to Einstein's theory of general relativity. Gödel is recognized as one of the century's most influential mathematicians; however, there were some who found his views untenable. The majority of mathematicians at the very least found it hard to come to terms with Gödel's conclusions.

Alan Turing

One mathematician who found it extremely hard to countenance Gödel's conclusions was British mathematician Alan Turing (1912–1954). Famous for his work during the Second World War on code-breaking at Bletchley Park, Turing's work led to the breaking of the Germans' Enigma code. Turing was also responsible for taking Gödel's bleak theorem even further. It is this, and for his large volume of work on computer science, that Turing is known for.

Turing directed much effort into the clarification and simplification of Gödel's theory of

incompleteness. His intention was to make it far less abstract and more concrete, and his solution, which he later claimed had come to him in a dream, would lead to one of the most significant inventions of the modern world, the computer.

Turing repositioned incompleteness in terms of computers, or at that time what were seen as theoretical devices that could manipulate symbols; these devices came to be called *Turing machines*. He replaced Gödel's universal arithmetic-based language with his formal, simple device and illustrated that this device could perform any conceivable computation that was representable as an algorithm. Next, he managed to prove that, although this highly logical machine was driven by arithmetic, there would always be certain problems it could never solve. When an unsolvable problem was fed into the computer, it would carry on attempting to solve it but would never succeed. Determining the general conditions for when this would happen was called the *halting problem*. Turing also discovered that we could not know in advance which problems were unprovable, thereby providing a negative proof of David Hilbert's *decision problem*. After the war, Turing worked on developing computers, such as the ACE or automatic computing engine, and the Manchester Mark 1. Despite the fact that computer technology was in its infancy, Turing was convinced of its potential. He foresaw a future where computers could think, play games, and communicate, and he was the first to develop a design for computer chess. Turing also was the first to look at the notion of artificial intelligence. The *Turing test* was developed by him to define the point at which a computer could be considered *intelligent*. This involved the computer's being able to fool a human into thinking it was also human. Unlike Gödel, who believed in the power of intuition and was convinced that the human mind had capabilities outside of the systems he described, Turing preferred to think of the mind as a formalized system such as the one embodied by a computer.

John von Neumann

John von Neumann (1903–1957), another child prodigy, became one of the foremost mathematicians of the 20th century. Neumann made huge

contributions to many fields of mathematics and also worked in quantum physics and on the Manhattan Project, which led to the development of nuclear physics. He is well known for his involvement in game theory and for his design for a digital computer that could hold both a processing unit and a storage structure that could hold instructions and data. This general plan is one that most computers still use today.

Andre Weil

The French mathematician Andre Weil (1906–1998) was active chiefly in the mid part of the 20th century. He made significant contributions to many areas of mathematics and was in particular interested in identifying the connections between algebraic geometry and number theory. He became fascinated by Diophantine equations, and it was this that led to his first notable work in mathematics, on the theory of algebraic curves. He went on to discover the topological algebraic adèle ring, which he built using rational numbers. He was also a founder and early leader of the Bourbaki group of mathematicians in France, a group that published many influential textbooks on advanced mathematical topics and whose aim was to unify mathematics via set theory. At the outbreak of the Second World War, Weil, a conscientious objector, fled to Finland. Later making his way back to France, he was arrested and imprisoned for refusing to perform military service. In 1940 while in prison in Rouen, Weil carried out work that sealed his reputation in mathematics. Building on the work of Évariste Galois in the 19th century, Weil decided to use geometry to analyze equations, thus developing algebraic geometry, which offered up a new language for understanding the solutions to equations. Weil's work on zeta-functions succeeded in proving the Riemann hypothesis for curves over finite fields, thereby laying the foundations for abstract algebraic geometry, the modern theory of abelian varieties, and the theory of modular forms. Weil's work on curves has influenced many areas of mathematics as well as other fields including string theory and elementary particle physics.

One of Weil's last contributions to the world of mathematics was the Tamagawa numbers, although his conjectures were not to be proven until 1989.

He also played a big part in the formulation of the *Shimura–Taniyama–Weil theory* on elliptic curves, later taken up by Andrew Wiles as part of his proof of Fermat’s last theorem. His development of what is known as the *Weil representation* later provided a contemporary framework for understanding classical quadratic forms.

Alexander Grothendieck

One of Weil’s greatest legacies was in his heir apparent, Alexander Grothendieck (1928–2014), a colorful figure in 20th-century mathematics. Grothendieck was a structuralist, interested in the structures that lie beneath the surface of mathematics. During the 1950s, he devised a new and powerful language that allowed mathematical structures to be seen in a new way. This meant that new solutions in number theory and geometry and even in basic physics could be discovered. Grothendieck’s *theory of schemes* was instrumental in allowing for Weil’s number theory conjectures to be solved, and his *theory of topoi* assumed an important place in the field of mathematical logic.

Grothendieck’s early work was in functional analysis and key contributions included topological tensor products of topological vector spaces, the application of L spaces in the study of linear maps, and the theory of nuclear spaces. Working between the years 1949 and 1953, Grothendieck soon became a leading figure in the world of functional analysis. It was, however, in algebraic geometry, where he was to complete his most influential work. Around 1955, he began work on *sheaf theory* and *homological algebra*, producing his influential paper “Sur Quelques Points de l’Algebre Homologique” in 1957. In this article, he introduced the ideas of abelian categories and used them to illustrate that sheaf cohomology is definable in terms of certain derived functors. Homological methods and sheaf theory had been introduced by Jean-Pierre Serre, among others, earlier in the century and sheaves themselves were defined by Jean Leray. Grothendieck was able to take them to a higher abstract level than before, turning them into key principles of his theory. He switched the focus from studying individual varieties to pairs of varieties related by a morphism, a shift that enabled a broad generalization of numerous classical theorems. The first such

theorem was the relative version of Serre’s theorem, where it was shown that the cohomology of a coherent sheaf is not infinitely dimensional.

Grothendieck also used the same thinking when he came up with an algebraic proof for the Riemann–Roch theorem, which was his first major achievement in algebraic geometry, as well as an algebraic definition of the fundamental group of a curve.

Grothendieck’s work in algebraic geometry was revolutionary in much the same way as Cantor’s, Gödel’s, and Hilbert’s, which is why he is considered by many to be one of the driving mathematical forces of the 20th century. Grothendieck was admired for his mastery of abstract principles and his perfectionism in formulating and presentation. His influence extended into many branches of mathematics, for example, the modern theory of D modules. He produced relatively little output after 1960 and retreated from public life to live in relative estrangement from the mathematical community.

Paul Erdős

Paul Erdős (1913–1996) stood out as a prolific albeit eccentric figure in the world of mathematics during the 20th century. Erdős hailed from Hungary and collaborated with many other mathematicians on various problems including graph theory, number theory, combinations, approximation theory, probability theory, and set theory. He became well known for offering prizes for solving unresolved mathematical problems including his own conjecture on arithmetic progressions, many of which remained unsolved in his lifetime. Erdős came from a Jewish family and was born in Budapest just before the outbreak of World War I.

Erdős was a legendary mathematician who remained devoted to his subject until he was into his 80s. He was one of the century’s most prolific mathematicians and produced more than 1,500 works during his lifetime. At age 20, he first made his mark in the field when he discovered a proof for a famous theorem in number theory. The theorem, Chebyshev’s theorem, states that for each number greater than one, there is always at least one prime number between it and its double. A prime number is a number that has no divisors other than itself and 1.

Erdős kept his interest in number theory for the whole of his life, posing and solving problems that

involved relationships between numbers; although they may have looked simple, these problems were very difficult to solve. Erdős believed that mathematical truths are discovered rather than invented, and he had a characteristic way of displaying this notion. He spoke of a Great Book in the Sky, maintained by God, where all the most elegant mathematical proofs were kept.

Paul Joseph Cohen

On the other side of the Atlantic, Paul Joseph Cohen (1934–2007) was a mathematician benefiting from the influx of European talent to the United States during the war years. He had a broad range of mathematical interests, from mathematical analysis to differential equations, number theory, to logic. In the 1960s, Cohen applied himself to Hilbert's list of problems yet to be solved, including Cantor's continuum hypothesis. This questioned whether there exists a number of numbers bigger than the set of all natural numbers yet smaller than the set of real numbers. Cantor had been convinced that there was not, but failed to prove his view, a view that had not been satisfactorily proven since then, although some progress had been made. Ernst Zermelo and Abraham Fraenkel had come up with the standard form of axiomatic set theory in the early 1920s. Termed the *Zermelo–Fraenkel* (ZF) *set theory*, this went on to become the basis for much of mathematics thereafter. Kurt Gödel showed in 1940 that the continuum hypothesis, because it is consistent with the ZF theory, cannot be disproved by it. This is the case even if the axiom of choice is selected (otherwise known as the *ZFC theory*). Cohen wanted to show that the continuum hypothesis was or was not independent of the ZFC theory, which would prove that the hypothesis was independent from the axiom of choice.

Cohen arrived at a startling conclusion, based on a new technique termed *forcing*, which he had developed himself. Cohen deduced that both answers could be true; in other words, that the continuum hypothesis and the axiom of choice were separate from ZFC set theory. From this, it became theoretically possible for there to be two different mathematics, which were internally consistent. One set of mathematics would see the continuum hypothesis as true and where there

would not be any set of numbers, and another where the hypothesis was false and a set of numbers existed. The proof looked to be correct, but because Cohen's methods were so novel, there was no consensus of opinion until it was finally given the stamp of approval by Gödel in 1963.

Cohen's findings were revolutionary, and ever since mathematicians have constructed two mathematical worlds in which the continuum hypothesis either applies or does not. Modern mathematics demands in fact that proofs must state whether the result is dependent or not on the continuum hypothesis. Cohen's proof was so successful that he decided to tackle something even more difficult, the Riemann hypothesis, and devoted more than 40 years to the problem, right up until his death in 2007. The problem still has no solution, however, although Cohen did give hope to other mathematicians, including some of his brightest students.

Julia Robinson and Yuri Matiyasevich

In the 20th century, several women, including Alicia Stout and Emmeline Noether made significant impacts on mathematics, but perhaps the most prestigious was Julia Robinson (1919–1985). Robinson spent much of her mathematical career in attempting to determine computability and decision problems, the questions that, in formal systems, have a *yes* or *no* answer, the answers being dependent on the parameters that had been input. She was also dedicated to answering one of Hilbert's mathematical problems, that of ascertaining whether it was possible to discover whether or not any particular Diophantine equation had a whole-number solution. There was a growing feeling that this was impossible—but neither was there a way to prove that it could never be possible.

In the 1950s and 1960s, Robinson, together with collaborators Hilary Putnam and Martin Davis, pursued the problem, eventually developing what was known as the *Robinson hypothesis*. This proposed that by constructing one equation with a solution of very specific set of numbers, of which one grew exponentially, it could be proved that no such method existed. Robinson later enlisted the help of Russian mathematician Yuri Matiyasevich (b. 1947) to help her solve the problem in its entirety. Matiyasevich was something of

a mathematical prodigy, having already won several prizes for his work. He used Hilbert's 10th problem as the basis for his doctoral thesis and had started to correspond with Robinson about her work on the problem. Matiyasevich eventually identified the missing piece of the puzzle in 1970 at the age of 22. He found a way to capture the Fibonacci number sequence using equations that formed the basis of the Hilbert problem. By building on Robinson's work, it could finally be proved that it is impossible by any method to determine in a finite number of processes whether Diophantine equations can be solved in rational integers. Despite the cold war between the United States and the Soviet Union being at its height, Matiyasevich was quick to acknowledge Robinson's input into his findings, and they continued to work together up until Robinson's death in 1985. Matiyasevich also made developments into prime number theory, devising a kind of *visual sieve* that crosses out composite numbers and leaves behind only prime numbers. His theorem on recursively enumerable sets is named after him, and he is credited with a polynomial related to the triangulation of spheres.

The 1970s and Beyond

The field of complex dynamics was taken up by the French mathematicians Pierre Fatou and Gaston Julia in the early part of the 20th century. However, it was not until the 1970s and 1980s that the field gained momentum. In addition to complex dynamics, chaos theory benefited from the ongoing development of computers, with their ability to carry out repeated iterations of mathematical formulas on a huge scale. Chaos theory deduces that certain systems appear to act randomly even when they are not actually random. Conversely, some systems can behave perfectly predictably in many ways but are unpredictable when it comes to detail. A chaotic system can be mapped graphically to understand its possible behaviors, and these mappings, or *strange attractors*, are by nature fractal. When the observer zooms in to get to more detail, the overall pattern stays the same at that magnification. Edward Lorenz was an early proponent of chaos theory. His interest in the subject came about accidentally because of his work in predicting the weather.

A computer model he was running was accidentally saved using three-digit numbers instead of the six digits he had been using. This small rounding error led to a wide variation in the results. Lorenz found that tiny changes in the initial conditions can produce big changes in long-term outcomes. He termed this effect the *butterfly effect* and managed to demonstrate this event using his Lorenz attractor, a fractal structure that bore correspondence to way the Lorenz oscillator behaved. The Lorenz oscillator is a three-dimensional system that illustrates chaotic flow.

In 1976, Kenneth Appel and Wolfgang Haken devised the first proof of the *four-color theorem*, which was the first major theorem proven by a computer. The four-color theorem had initially been the work of the 19th-century mathematician Francis Guthrie. It proposed that in a given segregation of a plane into continuous regions (called a *map*), the different regions require no more than four colors in order to color them, so that no two adjacent regions has the same color. Alfred Kempe provided a proof for this in 1879; however, this was disproved 11 years later by Percy Heawood, when he provided his five-color theorem. Appel and Haken's solution took more than 1,200 hours of computer time and the examination of approximately 1,500 configurations.

The 1970s also saw the increasingly popular use of origami as a mathematical method. This form of paper folding, which is usually associated with hobbyists, became as powerful as Euclidean geometry in certain ways. Margherita Piazzolo Beloch had shown, in 1936, how paper could be folded to get the cube root of its length. It was not until 1980, however, that it was proved that the origami method could be used to solve the problem known as *doubling the cube*. This puzzle had defeated mathematicians as far back as the ancient Greeks. This was followed in 1986 by a demonstration of how origami could solve an equally difficult problem—that of *trisecting the angle*. Japanese origami expert Kazuo Haga's folding techniques have derived many surprising results and won him the honor of having several mathematical theorems named after him.

In 1995, the British mathematician Andrew Wiles solved Fermat's Last Theorem, just 350 years after Fermat had posed the question. Wiles had been determined to solve this theorem from

an early age, and he refused to be defeated. He was not, however, solely responsible for proving the theorem and collaborated with many other mathematicians including Gerhard Frey, J. Pierre Serre, Yutaka Taniyama, Ken Ribet, and Goro Shimura. Wiles did provide the links and final synthesis and the eventual proof for semistable curves—a proof that runs more than 100 pages in length.

In recent years, another important conjecture, the Poincaré Conjecture, was also solved. In 2002, Grigori Perelman managed to provide proof of the thesis, which was then more than 100 years old. Perelman turned down the \$1 million prize, however, stating that for him, if his proof was correct, he needed no other recognition. The conjecture turned proof states that if a loop situated in a connected, finite, three-dimensional boundary-less space that can be tightened continuously to a point just like a loop drawn on a two-dimensional sphere, then the space is a three-dimensional sphere. Perelman's elegant but complex solution involved looking at the three ways, in which three-dimensional spheres can be enclosed in higher dimensions. He also contributed significantly to topology and Riemann's geometry.

John Nash was an American economist and mathematician who, although he suffered from paranoid schizophrenia, completed important work in differential geometry and in game theory. He also worked on partial differential equations, something which helped to illuminate the factors behind chance and events in such areas of daily life as computing, accounting, and military theory.

Nash earned a doctorate for his work on non-cooperative games, a dissertation that contained the definition and properties of what would be called the *Nash equilibrium*.

British mathematician John Horton Conway is responsible for bringing in the "Game of Life" rules in 1970. These principles that govern the pattern of cells evolving and growing in a grid are an example of *cellular automation*, and they were taken up by computer scientists. Conway also added his input to pure mathematics including group theory, geometry, number theory, and game theory. He is known for his invention of strange-sounding concepts including *monstrous moonshine*, *the grand antiprism*, and *surreal numbers*. He is also the creator of such games as Philosopher's Football and the Soma Cube. Rubik's Cube is another well-known

mathematical-based puzzle developed in the 20th century, which became incredibly popular with the general public. Rubik's Cube came into existence in 1974 and was the brainchild of Ernő Rubik, a Hungarian sculptor and professor of architecture. The puzzle, he predicted, would never be solved in his lifetime if it were only randomly twisted, so he began working on a solution, beginning with the alignment of the eight corner cubes. He then had to work out a sequence of moves for rearranging just a few cubes at a time and within a month he had solved the puzzle.

Sudoku was another mathematical puzzle that proved popular with the public and also generated serious attention from mathematicians, who sought to explore the theoretical limits of the game. The game of Sudoku is believed to have had its roots in the mathematical concept of Latin Squares. The Swiss mathematician Leonhard Euler developed a system in the 1780s that involved arranging numbers in such a way that any number or symbol would occur only once in each row or column. Latin Squares are actually used in statistical analysis.

The development and global dissemination of electronic computers in the 20th century have helped immensely in identifying phenomena such as Mersenne prime numbers. Mersenne primes are the numbers of less than a power of two. In 1952, a computer that was known as SWAC identified the 13th Mersenne prime number. This was the first to be discovered in more than 75 years and in time computers went on to identify several large numbers.

The internet has also brought with it a host of mathematical possibilities. In the 1990s, the Great Internet Mersenne Prime Search increased the rate at which Mersenne primes could be found. Run by volunteers and using freely available software, this has advanced research considerably. The 45th Mersenne prime was discovered in 2009 and was a landmark discovery, since it was also the largest prime number ever found, containing nearly 13 million digits. The search continues too for more and more accurate approximations of the irrational number π , a number that stands at 5 trillion decimal places and still counting. Another problem that computers have helped to advance is the P versus NP problem. This was introduced in 1971 by Stephen Cook and became a notoriously

complex unsolved theory. In its most basic form, the problem asks whether every problem whose solution can be checked efficiently by a computer can also be efficiently solved by a computer. That is, whether there are questions whose answer can be rapidly checked but which require an unending amount of time to solve by any kind of direct process or procedure. Although this problem, known as *Cook's Theorem*, or the *Cook–Levin Theorem*, may sound simple enough, computer scientists and mathematicians have struggled to find the answer to it for over 40 years. One possible solution, put forward by Vinay Deolalikar in 2010, purports to prove that P is not equal to NP (therefore, problems that are nonsolvable yet easily checked exist) has not as yet been accepted as being correct.

Finally, mathematics as a subject is clearly set to grow ever larger with computers becoming more important and powerful than ever before and the application of mathematics to bioinformatics growing exponentially. The end of the 20th century saw an explosion in knowledge, and there are currently hundreds of specialized areas in mathematics, and ever more mathematical journals published both in print and online. The 21st century has already seen the Clay Mathematics Institute announce the seven Millennium Prize Problems, and the Poincaré conjecture finally solved by Grigori Perelman.

MEASUREMENT

Measurement is widely performed to produce information about properties of objects, and the quality of measurement results may be evaluated: A theory of measurement provides criteria to distinguish measurements from processes like opinion making, and about the quality of measurement results. Moreover, it establishes the structure—whether quantitative or not only, and the domain, whether physical or not only—of properties to be measured.

The Scope of a Theory of Measurement

Measurements are performed in many different contexts to produce information about properties of systems, phenomena, processes, individuals, organizations, and so on. It is an integral part of modern science as well as of engineering, commerce, and daily life. Measurement is often considered a hallmark of the scientific enterprise and a privileged source of knowledge. But what is the source of the acknowledged *special efficacy* of measurement?

First, a theory of measurement is expected to provide a criterion of *demarcation*, able to distinguish measurement from other information-related processes like opinion making and computation: not all processes of information production are measurements. Second, the fact that measurement is a designed-on-purpose process, not a natural phenomenon, adds a pragmatic layer to the theory: A theory of measurement is expected to provide some criteria of *qualification*, able to characterize good and bad measurements (the quality of an opinion, for example, by a highly qualified expert, could be better than the

quality of a measurement as performed, for example, by means of a cheap instrument), and this prevents the defining of measurement simply as any high-quality information production process.

Moreover, a theory of measurement needs to be situated with respect to two strategic issues. First, is there any constraint about the *structure* of measurable properties? And therefore, in particular: is—for some reason to be identified—measurability a feature of quantitative properties (*quantities* for short) only, or can nonquantitative properties also be measured? Second, is there any constraint about the *domain* of measurable properties? And therefore, in particular: Is—for some reason to be identified—measurability a feature of physical properties only, or can psychosocial properties also be measured?

These issues probe the very idea of what measurement is, as developed across millennia of scientific, technological, philosophical, and societal changes, and as currently challenged by the widespread emphasis on datafication: Can an entirely informational process, with no empirical stages in it, be a measurement (perhaps a *virtual measurement*, as sometimes it is called)? Does a difference remain between a measurement and a simulation of a measurement?

In what follows, after some notes setting forth a fundamental terminological ground, the domain, whether physical or not only, and the structure, whether quantitative or not only, of measurable properties are analyzed in historical perspective, and on this basis, the problems of demarcation and qualification are discussed. The conclusion will be that what is measurement, and therefore what a theory of measurement should deal with, is still a moving target.

Background

Measurement is about attributing values to properties of objects: unpacking this is a precondition for a theory of measurement. The assumption is that *objects*, like systems, phenomena, processes, individuals, and organizations, *have properties*, like length, color, age, and intelligence (in a property-oriented ontology an object is something that has properties; whether objects can be identified independently of their having properties is an issue preliminary to our subject). Not any object

o has any property *P* (e.g., gases and companies do not have geometric shape), so that for each property the set of objects is partitioned into the subset of the objects that have the property—it may be called the *domain* of the property, $D(P)$ —or into the complementary subset of the objects that do not have it. This may be written in the predicative form $has_P(o)$, that is either true or false, so that

$$D(P) = \{o : has_P(o)\}$$

Hence, $has_electric_charge(electron)$ is true and $has_reading_comprehension_ability(Moon)$ is false. Such a classification—for any sufficiently well-identified *P* and *o*, either $has_P(o)$ or not—is the piece of information that provides the fundamental justification of the interest in dealing with properties.

Sometimes this information may be refined, by recognizing that a property *P* is associated with a set X_P of other properties, $X_{P,1}, X_{P,2}, \dots$, such that, for each *o*, $has_P(o)$ if and only if there exists one and only one $X_{P,i}$ in X_P such that $has_X_{P,i}(o)$. For example, for a physical body *o*, $has_color(o)$ if and only if $has_color_red(o)$, or $has_color_blue(o)$, and so on. In other words, for having color an object must have *a* color. Such coordinated—because exhaustive and mutually exclusive—properties $X_{P,i}$ may be called *manifestations* of *P*, or *determinates* of the *determinable* *P*. In this way, the domain of *P* is partitioned into equivalence classes, where each $X_{P,i}$ identifies the class of objects *o* such that $has_X_{P,i}(o)$. This process may be repeated by refining the partition: has_color_red can be considered a determinable in turn, whose determinates are $has_color_red_magenta$, $has_color_red_scarlet$, and so on. Note that multiple criteria of partitioning are usually possible, and therefore that the set of determinates of a given determinable is not necessarily unique.

Whenever $X_{P,i}$ is considered as an element of X_P , the predicate $has_X_{P,i}(o)$ is customarily written in the functional form of a *basic evaluation equation*

$$P(o) = X_{P,i} \text{ in } X_P$$

(e.g., $color(o) = red$ in $\{red, blue, \dots\}$), thus highlighting the conditions of existence and uniqueness in X_P of the determinate $X_{P,i}$ of the determinable *P* for each object *o* in $D(P)$. This

equation formalizes the core information that can be obtained by a measurement: the object o has the property P , and in particular the property $X_{p,i}$ in the classification of P according to X_p (e.g., o has *color*, and in particular has *color red* in the classification of *color* according to $\{red, blue, \dots\}$). This justifies the usual understanding of P as a function that when applied to the argument o has the value $X_{p,i}$ in the set X_p and provides a sufficient explanation of the somewhat confused related lexicon: Both P and $P(o)$ are considered to be properties (color is a property; the color of this object is a property that the object has), and $X_{p,i}$ in X_p is called a *value of a property*.

Measurement as Representation

The idea of *measurement as representation* plausibly originates from here: As it was stated by Norman Campbell, who devoted to measurement a large part of his book *Physics: the Elements* (1920), measurement is the process of assigning numbers to *represent* properties, where in fact *representation* and *assignment* are usual terms to designate functions. In this way, the content of the basic evaluation equation is weakened, by omitting any condition about the *equality* of properties of objects and values of properties, and actually interpreting such equations as

$$\text{representation}(P(o)) = \text{value}$$

(or sometimes even as $\text{representation}(o) = \text{value}$, by thus absorbing the reference to the property in the representation). In this broad sense, measurement is considered to be the representation of properties of objects by means of values that are assigned according to some consistency conditions, the simplest of them being that distinguishable properties must be represented by distinguishable values, so that no information is lost in the representation. A basic set of such conditions was proposed by Stanley Stevens in his seminal paper *On the Theory of Scales of Measurement* (1946), in which a sequence of scale types is identified, each of them characterized by an algebraic structure and a related condition of invariance. For example, if the properties x_i to be represented are not only distinguishable from each other but also ordered, then the values $f(x_i)$ by

which the properties are represented must be ordered accordingly:

$$\text{if } x_1 < x_2 \text{ then } f(x_1) < f(x_2)$$

As a consequence, any further monotonic function g applied to the values preserves the information conveyed in the representation; that is,

$$\begin{aligned} &\text{if } x_1 < x_2 \text{ and } f(x_1) < f(x_2) \\ &\text{then also } g(f(x_1)) < g(f(x_2)) \end{aligned}$$

so that the property x can be represented not only by $f(x)$, but also by $g(f(x))$. For this reason g is called an admissible scale transformation.

Many physical properties are more than ordinal only and admit a comparison by ratio (e.g., this is twice as much as that), sometimes based on an additive structure, such that objects can be composed according to their property and the composition has the features of a sum: $x_1 + x_2 = x_2 + x_1$, $(x_1 + x_2) + x_3 = x_1 + (x_2 + x_3)$, and so on. At least in classical physics this applies to lengths, masses, durations, intensity of electric current, and so on. In these cases, a property may be singled out as the unit, mapped to the value 1 of the scale, so that all comparable properties are represented by multiples or submultiples of the unit, and the generic value $X_{p,i}$ in X_p can be meant as k u; that is, the k th multiple of the unit u (e.g., 1.234 m). In such a ratio scale any similarity, such as

$$g(f(x)) = kf(x), \text{ with } k > 0$$

is an admissible transformation, so that a scale factor k is sufficient to transform for example values in meters into values in inches.

The following table, adapted from Stevens's paper, summarizes the main scale types and their defining conditions (where x is a property, v is a value, and g is a scale transformation).

This is the weakest, and therefore most encompassing, notion of measurement, also applicable to situations that someone would hardly accept as measurements at all (e.g., a person has performed a measurement because in their opinion this is less than that, so they labeled this as less than that). After Stevens, this position was given a more rigorous mathematical formalization by the so-called *representational theory of measurement*, in which the fact that a structure of properties can be mapped into a structure of values, through a

Table I The Main Scale Types and Their Defining Conditions

Type	Features	Invariance Condition	Admissible Transformations	Example
Nominal	Classifications	(Non)equivalence: $x_1 \neq x_2$	Injective transformations: if $v_1 \neq v_2$ then $g(v_1) \neq g(v_2)$	Blood type
Ordinal	Orderings	Order: $x_1 < x_2$	Monotonic transformations: if $v_1 < v_2$ then $g(v_1) < g(v_2)$	Hardness in Mohs scale
Interval	Numerical mappings without a “natural zero” and a “natural unit”	Ratios of differences: $(x_1 - x_2)/(x_3 - x_4) = k$	Linear transformations: $g(v) = k_1 v + k_2$, with $k_1 > 0$	Temperature in Celsius degrees
Ratio	Numerical mappings with a “natural zero” but without a “natural unit”	Ratios: $x_1/x_2 = k$	Similarity transformations: $g(v) = k v$, with $k > 0$	Mass
Absolute	Numerical mappings with a “natural zero” and a “natural unit”	Properties: x	Identity transformation: $f(x) = x$	Number of alpha decays

representation theorem, is considered sufficient to make it a theory of measurement: If it is a consistent representation—in this algebraic sense of consistency—then it is a measurement.

Measurability

If the long scientific, technological, philosophical, and societal development of measurement is read in light of the representational approach, a clash emerges: While consistency in representation may be acknowledged as a necessary condition of measurement, its *sufficiency* would be questioned by noting that, even if all measurements are consistent representations, not all consistent representations have been historically accepted to be measurements. Further possible constraints relate to the structure (whether quantitative or not only) and to the domain (whether physical or not only) of measurable properties. In both cases, the root is plausibly to be found in the mathematics of classical Greece.

Can a Nonquantitative Property Be Measurable?

Ratios were so fundamental in ancient Greek mathematics that *rational*, that is, *based on ratio*, was meant also as *reasonable*. And ratios were construed in terms of *measures*. Indeed, according to Euclid, in Book V of *Elements*, “a magnitude is

a part of a(nother) magnitude, the less of the greater, when it measures the greater,” whereas Aristotle, in book V of *Metaphysics*, explained that “a quantum is a plurality if it is numerable, a magnitude if it is measurable. *Plurality* means that which is divisible potentially into non-continuous parts, *magnitude* that which is divisible into continuous parts.” On this matter, distinguishing discrete versus continuous properties sounds today immaterial (hardly would someone claim that, say, the discovery that energy is quantized implies that it is countable but not measurable). Rather, what is important here is the nature of the entities whose measurability is considered. And that these concepts of magnitude and measure relate to mathematical, and not empirical, entities is clear from the fact Euclid himself considered that “a number is part of a(nother) number, the lesser of the greater, when it measures the greater.” Two millennia later, Augustus De Morgan was keen in pointing it out: “the term ‘measure’ is used [by Euclid] conversely to ‘multiple’; hence [if] A and B have a common measure [they] are said to be commensurable” (1836, p. 9).

In the past, the question whether the geometry of *Elements* is mathematical or empirical was possibly considered ill-posed, but with the break produced by the discovery of non-Euclidean geometries it became critical. And, despite some still existing stereotypes, the conclusion is clear:

Euclid was concerned about the mathematical concept of *measure*, not the empirical concept of *measurement* discussed here. Hence, the source of the *special efficacy* of measurement cannot be the Euclidean concept of measure.

Can a Nonphysical Property Be Measurable?

The emphasis on empirical entities of the experimental method promoted by Galileo Galilei led to reinterpret numerable pluralities and measurable magnitudes as physical quantities. In fact, a trace of the Euclidean focus on geometry remained in the traditional term “weights and measures,” as if weights (and pressures, temperatures, etc.) were not measurable because only dimensional quantities are. For example, in his *Mathematical and Philosophical Dictionary*, 1795, Charles Hutton called *observation* the process of evaluating a temperature by means of thermometer: It was not a measurement because only continuous geometric quantities were considered to be measurable. With such a strict implied meaning, it is not surprising that Otto Holder’s seminal paper (1901) *Die Axiome der Quantitat und die Lehre vom Mass* (translated as *The Axioms of Quantity and the Theory of Measurement*) maintained continuity and additivity as characterizing features of measurable properties. That most, if not all, psychosocial properties are not continuous, nor in fact additive, can be taken for granted: in no way is the intelligence of two individuals the sum of their intelligences, and so on (peculiarly, in those years physicists were discovering the discontinuity also of some physical quantities, at the fundamental level of quantum mechanics).

The measurability of such properties was the conundrum that led a committee appointed in 1930 by the British Association for the Advancement of Science to study “quantitative estimates of sensory events.” The conclusion was, substantially, that for a property to be measurable it must exhibit an additive structure or must depend functionally on one or more additive quantities (what Campbell had called *fundamental magnitudes* and *derived magnitudes* respectively). These conditions are possibly fulfilled by some psychophysical properties—along the line of the work started in the mid-19th century by Gustav Theodor Fechner

about the relationships between physical stimuli and the associated human responses—and in the mid-20th century triggered the development of methods to identify a hidden (interval) ratio structure in properties, particularly Rasch methods and the so-called *conjoint measurement methods*. But it also created a barrier that appeared impossible to overcome for many psychosocial properties, particularly in the context that we now call psychometrics.

A More Encompassing Concept of Measurability, Then?

The representational approach mentioned above proposed a constructive strategy to overcome these limits, at the price of neglecting (i.e., abstracting from) the way the process of measuring is structured and actually performed, a choice that makes the approach general but also generic. For sure, quantitative evaluations convey more information than non-quantitative ones, as the theory of scale types shows; but the multiplicity of the scale types also highlights the conventionality of the position according to which only quantitative properties, and possibly only properties evaluated on ratio scales, are measurable. Even in the context of fundamental physical metrology additivity and continuity are no longer taken as necessary conditions of measurability, as witnessed for example by the *International Vocabulary of Metrology*, which assumes that also ordinal properties are (quantities and are) measurable.

The clash between the strict conditions implied by the historical conception of measurement and the loose perspective of representationalism is not solved: both demarcation (to distinguish measurement from other information-related processes) and qualification (to distinguish good from bad measurements) still require a synthesis.

Toward a Theory of the Process of Measuring

Measurement is a process: hence, an actual theory of measurement, and not of measure, must be a theory of the process of measuring, and not only of the input–output relations that the process

establishes. In reference to the metaphor of the black box, a theory of measurement has to deal also with what there is inside the box, and not only with what enters and leaves the box.

As a generic basic evaluation equation, $P(o) = X_{p,i}$ in X_p , shows (a quantitative example being *length (rod a) = 1.234 m*), measurement provides information about the property P of an object o , by stating that $P(o)$ is a given $X_{p,i}$ and not any other $X_{p,j}$, $j \neq i$, in X_p . There are fundamentally two strategies to produce this kind of information. First, the value of $P(o)$ can be computed via a function of already available values (e.g., according to Newtonian mechanics the value of the length of the path traveled by a body moving at constant speed can be computed by multiplying the values of the speed and of the duration of the motion). Second, the value of $P(o)$ can be obtained by comparing the object o with other objects s_j , called *measurement standards*, each of them having a property $P(s_j) = X_{p,j}$ in X_p , so that $P(o) = X_{p,i}$ in X_p for a given i if $P(o) = P(s_i)$. For example, *length (rod a) = 1.234 m* if there is a measurement standard s_i whose length is 1.234 m and is the same as the length of *rod a*.

Within the Galilean tradition, the *special efficacy* of measurement is a matter of somehow identifying the *measurand*; that is, the property intended to be measured, and finding its value in the given scale in the here-and-now conditions of the process. To this goal, some calculations may be useful or even required—for example, to correct known environmental effects without an empirical intervention—but the first strategy is not sufficient: a pen-and-paper-only evaluation is not a measurement, because a measurement requires the property-related direct or indirect empirical comparison of the object under measurement and the measurement standards that materialize the chosen scale. (In the foregoing example, in order to consider that the length of the path is measured—in what it is traditionally called an *indirect measurement*—and not just computed, the information about the speed and duration of the motion must be acquired in the actual conditions, something that a computation cannot provide).

The two key features to qualify a measurement derive from this. First, measurement results are expected to be *object related*, by reporting the

outcome of the comparison of the object under measurement and some measurement standards. This explains the importance attributed to constructing and characterizing the behavior of measuring instruments, which have the goal of guaranteeing a sufficient object relatedness by removing the effects of all influence properties. Second, in most real-life cases measurements are expected to produce information that is socially transferable, and therefore interpretable in the same way by different individuals in different times and places, a condition that makes it *subject independent*. This explains the importance attributed to disseminating measurement standards and calibrating measuring instruments against them, so that the measurement results are metrologically traceable to the chosen scale, and in particular to the definition of the unit in the case of ratio quantities.

The quality of measurements and their results is fundamentally assessed about their object relatedness and subject independence, *objectivity* and *intersubjectivity* for short, through the several (usually quantitative) properties that characterize the process in its multiple facets: accuracy, specified as precision and trueness, in turn specified as sensitivity, selectivity, stability, resolution, and so on. The overall summary—traditionally related to measurement error—has been focused on *measurement uncertainty* in the several decades, hence with an encompassing epistemic emphasis on the information produced by the process and its trustworthiness: Measurement is thus conceived of as an empirical and informational process that is designed on purpose, whose input is an empirical property of an object and which produces values of that property that are explicitly justifiable in their (good or bad) objectivity and intersubjectivity.

MEDICINE, ANTIQUITY

Throughout the ancient world, many different theories were devised concerning the nature of illness, injury, and death. This resulted in the development of a wide range of methods of treating afflictions. Although many ancient societies also believed in some form of afterlife, the solace this provided could only go so far toward alleviating the grief and mourning of families and friends upon the death of an individual. This entry describes and explains the concepts and practice of medicine in the ancient civilizations of Mesopotamia, Egypt, Greece, Rome, China, and India, noting their influences on subsequent eras down to the present day.

Discoveries of fossilized teeth from prehistoric times show problems of erosion and tooth decay, with bone loss attributed to poor diet. The oldest

surviving item that shows some knowledge of medicine is a statue found in *Çatalhöyük* in present-day Turkey, dating from ca. 6500–5700 B.C.E. and depicting a seated female figure. It is thought to be a representation of the goddess of fertility giving birth and shows the mother seated on a specially designed chair.

Mesopotamia

Not much is known about medical treatments in ancient Mesopotamian empires of Sumer, Babylonia, and Assyria. There is one surviving piece of Akkadian literature, however, that focuses on the story of Gimil-Ninurta, which involved heating water over a fire. In the story, however, this is actually used as a ruse to rob a town mayor rather than to cure him of illness. Illnesses were commonly regarded as punishments from the gods, and as a result, there were many deities to which offerings would be given in the expectation of being rewarded with good health and prosperity. One Assyrian bronze amulet, now held by the Louvre Museum in Paris, shows the exorcism of a demon. In the Babylonian Code of Hammurabi (ca. 1772 B.C.E.), a legal document carved into a massive stone pillar, rules governing medicine are scant and refer chiefly to the outcome of operations, not to the medical and surgical procedures themselves. The code does mention removal of tumors, which had to be treated with a metal knife, and also mentions diseased flesh on a broken bone, possibly a reference to gangrene. From this and other information, however, it can be seen that there were three types of priests, one of which dealt specifically with the sick, having been taught at schools connected to temples. The Code of Hammurabi lays down penalties for medical practitioners if they failed to achieve a cure. These range from fines to amputation of hands if a patient died in surgery or lost his eye as a result of an operation. There is also mention in Babylonian texts of veterinary doctors who were regarded as having lower social status than physicians who treated humans.

Egypt

There were specialist physicians in ancient Egypt, even during the Old Kingdom (ca. 2700–2200

B.C.E.), and certainly there were doctors assigned to the rulers and who were known as “chief physician to the Pharaoh” and by similar titles. The demigod called *Imhotep* was believed to have been the creator of medical knowledge. Nevertheless, and in spite of the great skills that the Egyptians developed in embalming the dead, there were evidently severe limits to their anatomical knowledge. They obviously knew about the bones, as well as the larger organs such as the stomach, heart, and spleen. Some ancient Egyptian records do state that the veins and arteries—which were known to be linked to the heart—were believed to carry water, air, and also excretions through the body. Their anatomical knowledge, however, seems to have ended there.

Essentially, the major theories concerned with the treatment of medical afflictions in ancient Egypt rested on the *members* (organs) which were connected to the heart. One ancient text refers to 12 members being in pairs located in, and regulating, the breasts, legs, forehead, and other parts of the body. A later text mentions some 40 of these. The theory was that these were the root of many medical problems when they became blocked, heated, or extremely stiff. Thus, the medicine or treatment prescribed was intended to deal with these members.

Gradually, physicians in ancient Egypt came to believe that they could diagnose patients by seeing them without any detailed examination. This led to the compiling of medical texts that prescribed particular treatments. One of these notes, “When thou findest a man who has a swelling in his neck; and who suffers in both his shoulder-blades as well as in his head, and the backbone of his neck is stiff, and his neck is stiff so that he is not able to look down upon his belly,” he is to be told the importance of the swelling on his neck and ointment should be rubbed on it, after which he should be healed. Many of the medicines used by the Egyptians seem to have come from the olive tree, but there were also many other preparations that came from berries and other fruits, as well as herbs, with very few made from animal ingredients.

Greece and Rome

The ancient Greeks gained much of their initial knowledge of medicine from the Egyptians but

developed this considerably. The Greek physician Hippocrates of Cos (ca. 460–ca. 370 B.C.E.) is regarded as the *Father of Medicine* because his teachings and theories changed the view of many Greeks and established medicine as a separate discipline, distinct from philosophy. The first aspect of treating a patient was, according to Hippocrates, to observe and examine the patient in detail before making a diagnosis. Many of his cures depended on rest, exercise, and a proper diet, although he also identified a number of herbs and plants from which medicines for treating particular ailments could be acquired. Hippocrates also believed that it was important to keep detailed notes on the treatments, which would allow doctors to remember what had previously been prescribed for a particular person, and also to gain more knowledge about the success or failure of individual cures. Hippocrates wrote down many of his ideas and cures, and these came to be known as the *Corpus Hippocraticum*, or Hippocratic collection. He is also credited with the Hippocratic Oath, still in use today, by which physicians must promise to uphold specific ethical standards during their treatment of people.

From the 5th century B.C.E., the influence of the Greeks spread throughout the Mediterranean and then through the Persian Empire. By around 450 B.C.E., the Greeks had established Asclepios as the god of medicine and healing. He was claimed to have been the son of the god Apollo and a mortal mother, but some scholars believe that there might have been an actual person called Asclepios, and indeed there is some allusion to this in the works of Aristophanes (ca. 446–ca. 386 B.C.E.). Either way, buildings or temples known as Asclepeia came to be built in many towns and cities where people came to be cured. The curing of patients was seen as being partly the work of the doctors at the Asclepeia, and partly through divine intervention of the god to whom they brought gifts of food, which were placed on the altar. One interesting development was that patients themselves were encouraged to eat well and thus build themselves up physically, as well as to wash themselves in a bath house attached to the temple. Gradually, these practices became associated with two goddesses, Hygeia and Panacea, who are claimed to have been the

daughters of Asclepios and whose names are preserved in the terms *hygiene* and *panacea*. The Greek theory that there were both natural cures and supernatural cures continued through Roman times and remains to the present day with, for example, the Christian concept of miraculous cures.

Although medical knowledge at that time was capable of dealing with straightforward physical ailments such as broken limbs, cuts, and abrasions, there was a growing body of knowledge which showed that there were also mental ailments, which often exacerbated standard medical ones. Hippocrates came up with the theory that the body consisted of four *humors*—black bile, yellow bile, phlegm, and blood—although this later became associated with the Greco-Roman writer and physician Galen. According to the theory, people would remain healthy when the four humors were in balance. Yellow bile, representing fire (or summer), made people irritable or angry. By contrast, black bile, representing earth (or autumn), made people sad or melancholic. Phlegm, representing water (or winter), made people sluggish; blood, representing air (or spring), made people more optimistic.

On this view, if the humors were out of balance, then so was the mental and physical state of an individual. It was therefore important for doctors to try to achieve the proper balance. Occasionally, there were natural ways such as vomiting, and also the coughing of phlegm, sneezing, and nosebleeds, which were all attributed to the body itself trying to solve problems. Hippocrates mentions the need to drain the lungs of patients who are suffering from pneumonia. The theory of humors was to remain central to medical beliefs in Europe until the Renaissance. It was clear that more people tended to get colds during the winter, and some suffered from allergies to pollen (*hay fever*) during spring, with all these ailments accounted for by the belief in the importance of balancing the humors. There were obvious problems with this, such as during an outbreak of the plague in Athens in 430–427 B.C.E., when many people died and it was widely doubted that so many Athenians could have had their humors out of balance at the same time. This led to ideas that either the Spartans had poisoned the wells or that the gods had turned

against Athens, with others suggesting that poor air quality was responsible. Indeed, this idea of bad air pervades through ancient Europe, with people living near swamps tending to be more affected than those living in drier areas. This was to give rise to those suffering from *bad air* developing what became known as *malaria*. It was not until the 19th century that this came to be connected with the mosquitoes that flourished in swampy regions.

Archaeologists have found surgical instruments from the ancient world, and combined with surviving texts, it is clear that surgery was seen as important to the Greeks. Scholars have calculated that Homer, in *The Iliad*, mentions some 147 battle wounds in his text, with 106 of these being made by thrusts from swords, 17 from slashes by swords, 12 from piercing by arrows, and the remaining 12 by projectiles from slingshots. Most of these who were wounded subsequently died of these wounds, but an exception was King Menelaus, who was hit by an arrow in his waist. There is a reference to the doctor removing the arrow and then cleaning the wound, after which a healing ointment is applied. Similarly, there are references in later texts to limbs being removed after gangrene had set in.

Many Roman surgical tools have been found in archaeological *digs*. With their large armies, the Romans had significant numbers of army doctors for treating the many injured soldiers. However, little or nothing was known about germs and infections, with the result that surgical tools for treating the rich were often elaborate and had inlaid patterns that harbored plentiful microorganism, whereas simple tools used on poorer people were often cleaner.

Some medical theories were advanced by non-doctors. The dissection of human bodies was illegal in Greco-Roman times, and indeed this remained the case throughout medieval Europe. As a result, many doctors were clearly ignorant of the exact nature of the human body. This led the philosopher Aristotle (384–322 B.C.E.) to suggest that doctors should dissect animals to get a greater understanding of the human body—and it was Aristotle who is attributed with having come up with the concept that the heart was the central organ in the body and that the heartbeat was the sign of life. Gradually, there were more advances

in medical theories of the Greeks. Herophilus (335–280 B.C.E.) did dissect some human bodies and concluded that the brain and not the heart controlled the body, although the concept of the heart being the focus remained for centuries, especially for romantic attachments and in poetry. Erasistratus (304–250 B.C.E.) examined the heart and found valves but was unsure whether the heart pumped air or blood.

During the Roman Republic and the Roman Empire, there was a growth in cities, and one of the major problems that emerged was epidemics, especially the plague. The Romans had used their building skills to bring fresh water to cities and also to build sewers and public lavatories. They also had their own god of health, known as Salus. However, as noted earlier, in 295 B.C.E., a plague hit the city of Rome, and this led to the building of a temple in Rome dedicated to Asclepius. Even before Greece became a part of the Roman Empire, the Romans had absorbed many medical theories from the Greeks. Indeed, Greek doctors were favored during Roman times and it seems likely that some of the earliest ones were captured in war. Others moved to Rome, and indeed, Pliny the Elder (d. 79 C.E.) mentions that some Roman doctors had started taking Greek names. The old traditions relate that St. Luke was a doctor, although modern scholars disagree with this association. Claudius Galen was also Greek, having been born in Pergamon, a Greek city in Ionia (modern-day Turkey). He moved to Rome at the age of 20 and helped treat Marcus Aurelius and the imperial family during an outbreak of the plague. His work emphasized the ideas of the humors propounded by Hippocrates and others and indeed advised that doctors in training should go to Alexandria to consult the library there and also to dissect human bodies, which was evidently allowed in that city.

Women also came to be regarded as good at healing people, with Pliny the Elder writing in ca. 75 C.E. that “the science of charms and herbs is the one outstanding skill of women.” Pliny also suggests a number of cures with egg yolk mixed with wine and poppy juice being taken to treat people with dysentery and unwashed wool coated in honey being used to heal old sores. However, the theory of humors was still important; Pliny

believed that epileptics having a fit were trying to throw off an infection so as to bring the humors into balance again.

The Greeks and the Romans were also especially conscious of poisons, which in small doses could be used as a cure for disease but in large doses could kill. The Athenian philosopher Socrates was found guilty of an alleged offense and sentenced to death by swallowing a lethal dose of hemlock. Mithridates VI, King of Pontus, was so paranoid about being poisoned that he took small daily doses of certain poisons to build up his own resistance to them. Also, prisoners who were about to be executed could be used to test poisons and antidotes. This led to the development of what became known as *mithridatium*, an antidote that the king kept secret but was eventually uncovered by the Romans when they invaded Pontus. The emperor Claudius is reputed to have been poisoned with a recipe that included mushrooms, and Pliny the Elder famously mentions that there are some 7,000 different types of poisons.

China

In ancient China, there was a large range of medical procedures that were followed for centuries. Inscriptions from the Shang dynasty (1600–1100 B.C.E.) ascribe medical ailments to curses on ancestors, which are then passed down to later generations. This was a generalization based on the recognition of hereditary illnesses rather than the incidence of minor afflictions and injuries. The oldest surviving medical text in China was by Fu Hsi (ca. 2900 B.C.E.) who is believed to have devised the binary system of Yin and Yang, the fundamental, abstract, and complementary principles of the universe. When the Emperor Qin Shi Huangdi ordered the burning of books (and the slaughter of scholars) in 213–210 B.C.E., he specially excluded medical works from the destruction.

Chinese medicine had come to focus on the treatment of illnesses using herbs. Later came the development of acupuncture; massage, exercise, and dietary therapy were also important. These practices were intended to promote balance in the body between the forces of Yin and Yang, as outlined by Fu Hsi. Yang was commonly

understood as facing the sun, with Yin in the shade, or as manifested in the difference between fire and water. In many ways, the principle is not that dissimilar from the Greek views of the humors; what was essential was to attain the proper balance between these two forces. There was also the belief that those suffering from disease had tried to move from their assigned place in society, as the affliction was a reflection of a patient's context and surroundings as much as anything else.

Diagnosis was traditionally made by feeling the pulse in the right wrist and then the left wrist of a patient in the course of an examination of the skin. However, male doctors were not allowed to examine a naked woman; rather, female patients pointed to their symptoms and affected bodily areas on dolls that doctors kept for that purpose. And the Chinese easily differentiated between the epidemics such as the regular occurrences of the plague, the seasonal illnesses, and those which involved treating symptoms over long periods, especially for mental and nervous disorders.

The Chinese of ancient times had discovered much more about the circulation of the blood than was the case in Europe. The Chinese classical medical text, the *Nei Ching*, from around the 2nd century B.C.E., mentions that the blood flows through the body in a *continuous circle*. There was also a belief that some vessels carried air, although the concept of osmosis, and also that the blood-carrying vessels were closed, was not yet recognized.

The Chinese practiced acupuncture from the time of the Han dynasty. It is said to have its origins in some soldiers in battle being wounded with arrows but having been cured of other illnesses, and as a result, considerable research was undertaken in this field. Some pictographs from the Shang dynasty and also early surviving needles are likely to be connected with blood-letting and lancing wounds rather than acupuncture, which was originally done with bone needles from at least 200 B.C.E. The theory behind acupuncture is that, because the flow of *chi* (vital energy) is thereby altered, specific parts of the body are stimulated by insertion of the needles, although the respective insertion sites may be

remote from the affected organ or region. This therapy has been found to be effective in reducing some levels of pain, and it has remained popular since ancient times as an alternative method of medical treatment. Traditional Chinese medicine using herbs and other preparations has also continued to prove to be effective in dealing with certain conditions.

India

In the south Asian region of India, medical beliefs focused on what the ancient Indians saw as the five classical elements: earth, water, fire, air, and ether. They also recognized seven basic tissues: plasma, blood, muscle, fat, bone, marrow, and semen. The aim was to remain healthy by keeping a balance between these through moderate behavior. In many ways, this was similar to classical Greco-Roman and Chinese views. Indian views on afflictions were that some arose from a lack of moderation in connection with rest, diet, or other factors such as sexual intercourse. They also felt that some natural urges—such as to sneeze—should not be suppressed but rather indulged as this was a natural way in which the body tries to achieve harmony. Massage and rest were particularly important cures, with a large range of medicines made from parts of plants such as bark, roots, or leaves, as well as from fruit and seeds.

Ancient Hindus had a pantheon of gods, with Agni emerging as the Hindu god of fire, and who was believed to be able to cure fevers. And the earliest complex medical equipment in the world was found by archaeologists who discovered a dental drill dating to as long ago as 7000 B.C.E. used by the Indus Valley civilization in modern-day Pakistan. It consisted of a hand-operated drill which has flint points and can be used to remove decaying dental tissues. Indian medicine also placed particularly heavy emphasis on hygiene, including regular bathing and also the daily cleaning of teeth.

MEDICINE, CONTEMPORARY

Medicine is usually defined as the practice concerned with the preservation of health and the prevention, alleviation, or cure of disease. Contemporary medicine is also known as *allopathic* medicine. The term comes from the ancient Greek prefix ἄλλος, *other*, *opposite*, and the suffix πάθος, *to suffer*. In short, it refers to treating a symptom with its opposite as, for instance, treating an infection with antibiotics or curing constipation with a laxative.

The term *allopathic* has long been considered derogatory by many in mainstream medicine, as much of standard medical practice does not seem to work in that way. Nonetheless, one can say that contemporary medicine is focused on curing patients, intervening by *removing* the cause of

the disease. If that is the main goal of medicine, then it does require an understanding of basic concepts such as *health* and *disease* to identify who needs help, and more complex ones, such as *cause* and *evidence*, to know how to intervene efficiently. Theories of health and disease, and theories of evidence and medical knowledge, have profound societal implications because whether and how an individual has to be treated depends mostly on their content. While it is certainly true that medicine is a practical and societal enterprise, it is at the same time a scientifically founded discipline. Furthermore, in medicine one can find theories in both a foundational and a special sense. Foundational theories lay the groundwork of the discipline, while special theories aim at providing an account of observed phenomena. Notably, both the categories of medical theories are strictly connected with practical action (understanding, treating, and preventing disease), unlike most other scientific disciplines wherein theory is more distant from applications (consider, e.g., theoretical physics). In fact, the theory of medicine is subordinate to the constitutive ethical imperative of medicine, which demands action to help people in case of sickness or accident. Nowadays, no other scientific discipline has an influence on ordinary life even remotely equal to that of medicine.

Theories of Health and Diseases

Medicine serves a very practical purpose: to heal the sick. But to accomplish this goal, a theory to distinguish sick from healthy individuals is needed. That has indeed been one of the main theoretical goals of medicine, since the humoral theory associated with the ancient Greek physician Hippocrates (ca. 460–375 B.C.E.) and the eclectic theory of the best constitution associated with the physician and philosopher Galen (129–216 C.E.), in the time of the Roman Empire. For many people, the disease is a given, a state of affair easy to identify. That is not actually the case, though.

In the last two centuries, there has been a strong medicalization of society. Some conditions that were previously not considered illnesses became recognized as medical conditions. Today, medicine is prevalent in nearly every area of our lives.

Medicalization, taken at face value, is not inherently a negative idea, and it has certainly enhanced our quality of living. But the basis on which human problems are to be described and handled as medical issues must be very clear. Otherwise, vested interests can distort the benign essence of medicine. Indeed, the definition of the terms *health* and *diseases* has been a central topic of theoretical reflections on medicine since the 1960s.

There are three major competing theories of health and diseases in contemporary medicine: naturalism, constructivism (or normativism), and hybridism. Some scholars, often called *naturalists*, argued that definitions of health and diseases must be based on biological facts. Only science can tell what counts as a disease, and the more we know about human biology the better the definition. According to *naturalism theory*, health and disease are empirical, objective, and value-free concepts, and thus they are to be understood in purely scientific terms. The most prominent naturalist account of health and disease is perhaps Christopher Boorse's *biostatistical theory*, developed in the late 1970s. Within this account, a person is healthy when she has normal biological functions. And normality is defined by observed frequencies in a specified reference class (e.g., within a specific age group and sex). The theory needs appropriate reference classes because human beings have wide variability in biological functions: what is normal in one group can be abnormal in another. For instance, normal levels of estrogens in adult females are different from normal levels in infant females. A young woman who has the same level of estrogens that is normal for an older woman would be deemed diseased. So, to assess when a process or a part of the organism, such as an organ, functions in a normal way, one must compare it with the organs of similar people in the same age group. If it works similarly, then the organ is normal, and the individual is healthy; otherwise, the organ is diseased. Indeed, according to the biostatistical theory, disease is just a departure from health or normality.

The main alternative approach to the naturalist theory of health and diseases is *constructivism* or *normativism*. Most proponents of this theory agree that the terms *health* and *disease* must be defined explicitly and that definitions strongly depend on values. On this theory, being healthy

requires the possession of various capacities, not only normal biological functions. This theory is epitomized by the World Health Organization (WHO, 1948) definition of health: "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." This definition expands the concept of health beyond biological considerations. The concept of health seems then closer to the idea of well-being, which is an evaluative notion. At the same time, the concept of diseases is not confined only to biological dysfunctions. On the extreme formulation of the theory, the *constructivists* believe that the definition of disease is nothing but a result of our value judgments. More specifically, the diseases are those conditions we as a society do not like much. Therefore, this account seems better to grasp all those diseases that do not have a clear biological basis—such as depression for instance. Further, it can accommodate individuals' feelings and culture-bound syndromes. However, unlike naturalism, the constructivist theory is not a unified account and there are many possible varieties, which cannot be discussed here owing to space limitations.

Finally, the *hybrid theories* of health and disease combine some aspects of both theories, in the attempt to overcome some of their major issues. Since both of those accounts suffer from serious objections, some scholars (e.g., Jerome Wakefield) have developed hybrid theories taking important elements from both naturalism and constructivism. From naturalism, hybridism takes the idea that health and disease must involve the biological functioning of the organism. From constructivism, hybridism holds that biological dysfunctions must be disvalued for a condition to be considered a disease. On this account, biological abnormality, although important, is not sufficient for a condition to be a disease, nor is it sufficient for there to be the mere capacity of a condition to cause harm. Therefore, the hybrid theory holds that there are two necessary conditions that a state must have so as to be deemed a disease: It must be a biological dysfunction and the state must be disvalued or harmful, but neither one is sufficient. Even though hybridism inherits some of the drawbacks of naturalism and constructivism, it has an additional advantage: It is more consistent with the actual medical practice.

All in all, however, these efforts to establish theories of health and diseases have demonstrated that there is no common concept that best encompasses their essence. New interpretations are introduced as either science or behaviors change over time, giving to these terms an irreducible complexity that demands continuous analytical attention.

Theories of Causation

If the central goal of medicine is to help the sick, then it is fundamental to determine what knowledge is required to achieve this goal. That is why all the medical theories in contemporary medicine are theories that aim to explain or understand a disease in order to treat it. In contemporary medicine, explaining or understanding a disease is all about recognizing its cause. But to develop such a piece of knowledge, it is essential to know some basics about the general nature of causation.

There are three main theories of causation in medicine. One is the *sufficiency–necessary theory*, which holds that a cause is a condition either necessary or sufficient (or both) for its effect. Necessary means that the disease Y will never develop without the condition X. Sufficient means that every time the condition X is present, the disease Y will always develop. Three different types of causal relations can then be derived: necessary and sufficient, necessary but not sufficient, sufficient but not necessary. In all the possible scenarios we can then apply this causal theory to identify a condition as the cause of a particular disease. This view is traditionally associated with the germ theory of disease, wherein diseases are caused by specific agents. This very important theory in the history of Western medicine is attributed to a German physician and microbiologist of the 18th century, Robert Koch, who developed the famous four postulates of disease that link a particular disease to a very specific pathogenic microorganism. However, physicians have understood, at least since the advent of the age of chronic diseases, that not all diseases can be attributed to a particular, necessary, or sufficient cause. Cigarette smoke, for example, is not necessary for the occurrence of lung cancer, nor is cigarette smoke its sole cause. In fact, the causes of complex chronic diseases, such as cancer and heart disease, appear to fall under the “neither necessary nor sufficient”

category. But even in infectious diseases, the presence of a pathogenic agent is not a necessary nor sufficient condition, since in some context the pathogen alone is not able to cause the disease, as for instance in asymptomatic carriers, people who have actually been infected but do not display the symptoms of the disease.

The second theory is the so-called *probabilistic theory of causation*. On this account, a cause is a condition that raises the probability of developing the disease. A cause is, therefore, neither necessary nor sufficient, but it just increases the probability that its effect will occur. For example, smoking is not necessary nor sufficient for developing lung cancer: Some smokers never develop it, and some nonsmokers develop the disease nonetheless. But smoking certainly increases the probability of the occurrence of the disease. Within this theory, the concept of cause goes along with the idea of risk factor. Epidemiologists use this term to indicate a condition that is probabilistically associated with a given outcome. But not all risk factors are necessarily also causing the disease in the strict sense (e.g., low socioeconomic status is often associated with an increased risk of cancer, but it is not a cause of the disease). While this theory might sound appealing, it might not always be able to distinguish a genuine relationship from spurious correlations. For example, many observational studies have found a correlation between drinking alcohol and cancer. Cancer could be due, in fact, to drinking, but it could be also due to some features of drinkers, such as poor diet or smoking. Answering the question of whether a given factor is or is not a cause requires making a judgment. There are no rigid and objective criteria for determining whether a causal relationship exists; nonetheless in 1965 Austin Bradford-Hill proposed a list of nine aspects of associations that should be measured when attempting to draw conclusions regarding causality, which has since become very popular among practitioners. The list includes the following nine aspects: the strength of association, consistency, specificity, temporality, biological gradient, plausibility, coherence, experiment, and analogy.

The third theory is the *sufficient-component theory of causation*. According to this view, the cause of a disease is the total collection of

different conditions that are together sufficient for the occurrence of the disease. So, a sufficient-component cause is like a pie, composed of several different ingredients, none of which is sufficient for the disease on its own. However, when all the ingredients are present, the disease will occur. Each of the ingredients of the pie is nonetheless necessary on its own to the cause, since in fact by removing one of them the disease will not occur. This view has been promoted by an epidemiologist, Kenneth Rothman, based on a philosophical account of causality developed by John Leslie Mackie. According to Mackie, a cause is an insufficient but necessary part of an unnecessary but sufficient condition for an effect. That is why a cause is not necessary *per se*, since more than one set of components may be sufficient for the same effect; that is, a disease may have multiple causes. Considering once again the smoking–lung cancer example, smoking has to be combined with other necessary components (e.g., genetic predisposition) in order to cause lung cancer.

Recognizing genuine causal relationships from spurious associations is of course paramount to the success of medical practice, as treatments and public health policies are addressed mostly to remove the causes of diseases. So, theoretical reflections on causality in medicine are not only interesting *per se* but may also impact on the well-being of patients.

Theories of Medical Knowledge and Evidence

Everyone agrees that medical doctors should act in accordance with scientific evidence but disagrees about what evidence precisely is. Given a medical problem, what is the best way to solve it? What does count exactly as scientific evidence? Answers to this kind of questions are usually a matter for philosophers and epistemologists. Yet some medical practitioners at the beginning of the 1990s took these issues with regard to medicine very seriously as well. The *evidence-based medicine* (EBM) movement was the result of that reflection, and it has revolutionized and shaped contemporary medical practice. Its proponents have established a new medical epistemology according to which medical decisions must be

made on the basis of a very particular type of evidence, more precisely that provided by randomized controlled trials (RCTs).

One of the most important types of research in medicine is indeed to find effective ways to intervene in the disease. Therefore, the problem for medicine is what knowledge is valid to assess the effectiveness of interventions. For hypotheses regarding the effectiveness of interventions, there is indeed a great variety of evidence, sometimes even conflicting with each other—from *in vitro* and *in vivo* research, to observational studies, to case reports and individual experience of physicians. However, not all kinds of evidence are equally valid. In fact, according to EBM, medical research is prone to bias much more than any other scientific enterprise. Thus, evidence should be ranked according to its potential to prevent bias, and this potential depends eventually on the research design. Study designs that rank higher on the hierarchy of evidence are more likely to provide reliable evidence. Over the years, stemming from the original work of David Sackett (the physician considered to be the father of EBM), researchers have identified a list of biases that can occur when experimenting and have agreed on a list of debiasing controls and procedures to be implemented. From an ideal point of view, the methodology of RCTs can deliver more unbiased results, at least when compared with other study designs. This is because there is more room to implement debiasing procedures in RCTs than in any other study.

The theory of medical knowledge and evidence-based contemporary medicine rank scientific study types in a very rigid hierarchy. On top of the so-called *evidence pyramid*, there are meta-analyses and systematic reviews of RCTs (a way to summarize research results). Single RCTs are just below, followed by cohort studies, case-control studies, case series, and case reports. Surprisingly, mechanistic studies (i.e., laboratory basic research conducted *in vitro* and *in vivo*) lie instead at the bottom, because they are considered less relevant for clinical research than any other kind of study, even if they are fundamental for understanding diseases.

Despite its appeal, EBM continues to invoke many criticisms. According to many scholars, the EBM theory of evidence is too narrow as it excludes information important to medical

practitioners, such as professional experience and patient-specific factors. For this reason, the usefulness of EBM application to individual patients is considered limited. And because there are so many uncommon diseases and variants, for many patients we do not have any evidence, since actual cases hardly match with the patients included in experiments. Nonetheless the criticisms, EBM is still the dominant paradigm in the field, more than 20 years after its conception.

In the end, EBM makes a normative argument as to whether it is truly possible to take certain kinds of evidence as reliable medical knowledge. In this sense, it is a theory of knowledge. But it also takes a normative stance on medical practice: Wherever possible, medical decisions should be based on the best available evidence (i.e., RCTs) about the available interventions. EBM places medical knowledge at the center of medical practice, adopting a very strict theory of what can be regarded as medical knowledge.

This appeal for a *theory of medical knowledge and evidence* is very important to patients. Failure to determine causal arguments can indeed be harmful—contributing, for example, to the administration of ineffective treatments. Also, medical errors are especially troubling for medicine itself, because they are *visible* to the public, and too many mistakes will lead to the growth of medical skepticism in society. Having a clear theory of medical knowledge and evidence will not only help doctors make better choices but also strengthen medical practice.

Reductionism and the Biomedical Model

Along with the broad theories composing its foundations, contemporary medicine has also produced many narrower special theories aiming at understanding and explaining phenomena of medical interest. Among the latter, for instance, neurophysiology theory explains how biochemical transmitters may affect mood, behavior, and pain; mechanical laws prescribe the functioning of muscular activity; immunological theory explains how vaccines work; theories of cancer metabolism elucidate tumor growth; and so on. Such theories derive from contemporary laboratory life sciences, such as molecular biology, which are conducted with the methods of the exact sciences and the vital support of new

research technologies. This is because contemporary medicine widely embraces *reductionism*.

In a nutshell, reductionism is the philosophical idea that all higher level (e.g., social, mental, and even medical) phenomena and processes can in principle be explained at a lower level. This theory is a very powerful tool for investigating phenomena in medicine. The basic idea of medical reductionism is that diseases are microphysiological problems to be solved by a direct intervention in the underlying biological mechanisms. Medical theories deconstruct a disease into biological parts and processes and compare them with the corresponding parts and processes of people without the disease. Accordingly, diseases are to be investigated by identifying the pathological microphysiological parts and processes that constitute them, and consequently, medical treatments should target those microphysiological parts and processes.

Reductionism in medicine is also often referred to as the *biomedical model* of medicine, because of its insistence on the biological basis of medical phenomena. This view has been the dominant trend in medical research during the last 50 years, at least since the first advances and successes of molecular biology. Many disorders have indeed been adequately explained in reductionist terms, and this in turn has led to some very successful medical treatments. For example, antibiotics, insulin, vaccines, and immunotherapies are just a few of the many success stories of reductionism.

However, despite its early undeniable successes, the biomedical model has been widely criticized. Its opponents argue that there has been an overemphasis on the pursuit of genetic or molecular-level explanations of disease to the exclusion of alternative, yet significant, levels of explanation. Moreover, according to its critics, the biomedical model leaves out important information about the disease at the phenotypic level that is essential to the pursuit of effective treatments. For instance, many diseases that have been viewed as *genetic*, such as cystic fibrosis and Alzheimer disease, cannot actually be reduced to unified entities with a specific genetic cause. Moreover, since there is probably a genetic variation component in susceptibility to virtually all diseases, the very concept of genetic diseases dissolves. Furthermore, according to the critics,

reducing the differences between individuals merely to their respective genomes is impossible, since all phenotypic traits are the result of an interaction between genes and the environment within which they are expressed. From this perspective, a more *holistic* approach that takes into account social and environmental factors can deliver a better understanding of diseases, as well as better treatments.

Criticisms notwithstanding, today the reductionist theory and the biomedical paradigm remain the dominant approach to medical research and practice. In the early 21st century, there has been even greater emphasis on reducing diseases to the genetic and molecular level. In fact, the biomedical paradigm has become even more popular, mostly due to a series of significant achievements in biomedical research, such as the completion of the *Human Genome Project in 2003*, identifying and mapping all of the genes comprising the human genome.

Recently, new advances in genetics and the growing availability of health data have triggered a major improvement of the biomedical model: *personalized* and *precision* medicine. The basic idea, epitomized by the slogan “treatment for the right patient at the right time,” is that treatments can be *tailored* based on individual genetic differences, or other kinds of molecular information. This data-driven approach to treatment has been proved to be efficient, especially in oncology. One reason is that cancer is undoubtedly linked to genetic factors: Cancer harbors many mutated genes that contribute to the genesis and development of the disease. Moreover, recent technological breakthroughs, namely next-generation sequencing and single-cell sequencing, have made it possible to observe genetic variations at the single-nucleotide level between different types of tumors, as well as between individual tumors. Tumors harboring certain mutations are more vulnerable and respond better to specific therapeutic agents. And this variability can then be exploited in order to provide the best therapeutic strategy for each patient. With regard to this, the drug *vemurafenib* is a classic example, as it has been developed precisely in order to treat a very specific subset of cancer patients, those with late-stage melanoma harboring the V600 mutation of the BRAF gene. Precision medicine is still in its early

stages, and so far it has not revealed all its potential, but it continues to grow year after year. If it keeps its promises, precision medicine could revolutionize medical health care.

MEDICINE, ENLIGHTENMENT

The 17th and 18th centuries saw important developments in natural philosophy specific to medicine, and in the work of physicians and surgeons, which formed the foundation for the scientific approach to medicine that emerged in the 19th century. Major developments in adjacent fields of research and experimentation, chiefly physics and chemistry, also proved to be of immense importance to the burgeoning fields of medicine and biology. The Enlightenment of the 17th and 18th centuries in Europe witnessed the emergence of fundamentally new ways to see the human body in terms of both physiology and pathology. Consequently, theories about what a disease is (*nosology*) and how pathological states developed (*etiology*) also changed.

However, some forms of medieval medical knowledge continued far into the Enlightenment period: humoral theory and the anatomic contributions of the Greek physician, surgeon, and philosopher Galen (129–c. 216 C.E.). Long-standing and entrenched ideas from Galenic anatomy were challenged and began to recede in the 16th century. The work of anatomists such as the Dutchman Andreas Vesalius (1514–1564) and Scotsman William Hunter (1718–1783) did much to supplant Galen's anatomical teachings, while the early nosology of English physician Thomas Sydenham (1624–1689) and subsequent disease classifications

by physiologists such as the Frenchman François Boissier de Sauvages (1706–1767) completely transformed ideas about disease and illness, away from humoral perspectives toward vitalist and mechanistic ideas of the body by the end of the 18th century. At the same time, the study of anatomy made considerable advances through the efforts of surgeons, whose practitioners grew to lay particular claim to anatomical knowledge because of its practical application in surgery.

All of these changes, spurred by the activities and writings of dispersed, and sometimes completely disconnected, experimental practices and researchers, coupled with revolutionary epistemological shifts to the questions *what is knowledge?* and *what is life?*, coalesced by the end of the Enlightenment to emerge as the scientific medicine that we are familiar with today. This entry focuses on two main elements of Enlightenment medicine: theories about the body and its health, which developed mainly with attention to the theory of humors and advances in anatomy; and classification of the body, informed by progress in surgery on the one hand and by theories and treatment of disease on the other.

Theories of Health and Body

Humoral Theory

While more inductive and scientific modes of understanding the human body started to appear in the 17th century, Galenic humoral theory persisted and maintained relevance until the later part of the 18th century. Humoral theory, which can be traced back to Greek antiquity, remained an important part of physiological thought throughout the Enlightenment period.

The idea of the four humors originated in ancient Greek pre-Socratic philosophy and was part of an overarching cosmology that sought to explain or account for all existence. The Greeks conceived of everything in the world being comprised of four elements: water, earth, wind, and fire. The writings attributed to Hippocrates extend this reductive framework to the human body and health in the form of the four humors: blood, phlegm, and yellow and black bile. These four bodily fluids were believed to underlie each individual's particular embodied experience, in health and illness, and even in our dispositions and attitudes.

Health in humoral theory centered on the idea of balance; balance in a person's diet, sleep, and exercise was reflected in an overall balance and equilibrium of the four bodily humors. Humoral balance constituted good health. If this equilibrium was broken due to either deficiency or excess of one or more of the humors, disease would ensue. For example, a tumor was understood to be an accumulation of black bile in a particular area of the body. An excess of yellow bile could cause erysipelas (red rash); a buildup of phlegm caused edema (fluid buildup).

Humoral theory continued during the Roman Empire and is most associated with the writings of the Greek physician Galen. Galen was born in Pergamon, now Bergama in Turkey, where he trained as a physician before eventually moving to Rome to work as a doctor. As a prolific researcher and writer, he rose to a high level of fame and attended to many significant figures of the age, including Emperor Marcus Aurelius (121–180 C.E.). Galen was a prolific writer; many of his books explored the topics of medicine and anatomy; others discussed philosophy and politics. A devastating fire in Rome in 191 destroyed a substantial portion of Galen's writings. Subsequently, the gradual collapse of the Western Roman Empire through the 4th and 5th centuries resulted in the disappearance from the European landscape of a large part of Galen's writings. During the medieval period, or what has traditionally been called the *Dark Ages* in European history, Hippocratic and Galenic writings survived in the Eastern (later the Byzantine) Empire and in the Arab and Persian Middle East. Numerous Arab and Persian philosophers, such as Rhazes (Abū Bakr al-Rāzī; c. 864–c. 935), Avicenna (Ibn Sina; 980–1037), and Averroes (Ibn Rušd; 1126–1198) among others, translated these writings from Greek into Arabic and spread Hippocratic, Galenic, and Aristotelian knowledge more generally. Gradually, this knowledge traveled back to Europe through Moorish Spain where it was incorporated into Christian philosophy, which became highly influenced by Greek natural philosophy, especially Aristotelian, as Christian philosophers like Thomas Aquinas (1225–1274) and William of Ockham (c. 1285–1347), incorporated it into a strict conceptual framework that would become known as *scholastic philosophy*, for its emphasis in Europe's burgeoning university culture.

Within the medieval period, the doctrine of the four humors was sometimes referred to as the four temperaments as it was believed to explain each person's particular disposition. Therefore, one could be deemed a melancholic (depressed) due to an excess of black bile or a phlegmatic (cold and tired) due to an abundance of phlegm, both humors characterized by coldness, dampness, and an overall analogous relationship to the winter season. Black bile and its association with coldness and dampness had a particular influence in concepts of pathology. These are just a few examples of how the humoral doctrine formed a complete cosmology/explanatory framework within medieval Europe for understanding the relationship between the body, health, disease, and the natural environment.

Humoral theory began to recede starting in the 17th century with the rise of experimental philosophy and the development of competing physiological frameworks, such as English anatomist William Harvey's (1578–1657) ideas about the circulation of blood (discussed below). New approaches to classifying and understanding diseases, as found in the writings of the "English Hippocrates" Thomas Sydenham, enjoyed widespread influence in subsequent developments in European medicine and pathology. As a formal medical theory, Galenism was largely discredited by 1700. Compared to the emerging approaches to natural philosophy exemplified by experimentation and systematic reasoning, Galenism was inaccurate and unreliable. It could not account for many new observations that were arising from new approaches and techniques. However, in the clinical domain, as a theory applied to the practice of diagnosis, the notion of humoral equilibrium, the *body in balance*, continued to pervade medical practices about health and illness. While famous Enlightenment doctors like Sydenham, William Cullen (1710–1790), and Giovanni Battista Morgagni (1682–1771) may have considered Galenic ideas outdated in theory, working physicians still drew from humoral theory when diagnosing and treating individual patients. Indeed, these holistic ideas of balance and equilibrium remained important physiological concepts even in 19th-century cell theory, and in Claude Bernard's *scientific physiology*, which depended on the functional interaction and balance between

numerous organs and the chemicals they produced within the body. These originally humoral ideas about balance and equilibrium persist, even if only analogically, in modern understandings of physiology such as homeostasis and cell autophagy. While the Enlightenment brought about many changes in medicine, certain core ideas survived in a different guise.

Anatomy

The traditional view within the history of science is that the prominence and authority of humoral theory and Galenic teaching began to decline during the 16th century. This shift in medical thought corresponded with widespread social upheaval throughout Europe. Notably, as Martin Luther's 95 Theses were translated into various vernacular European languages in the 1520s, Swiss-born physician Theophrastus von Hohenheim—"Paracelsus" (c. 1493–c. 1541)—staged public protests across Germany during which he reportedly burnt Latin copies of Galen and Avicenna in a dramatic show of opposition to the old order of medicine. Medicine, religion, and politics were very closely tied.

Various other significant events in natural philosophy, including the revolutions wrought by Polish astronomer Nicolaus Copernicus (1473–1543); the beginning of transatlantic exploration and colonialism following the Portuguese voyages of discovery; and the late-Renaissance humanistic ideas exemplified by the works of Leonardo Da Vinci (1451–1519) and anatomist Andreas Vesalius, all either directly challenged Galenic doctrine or the broader Christian scholastic systems of which it was part.

Centuries earlier, the discovery and assimilation of Galen's writings were themselves part of a late-medieval intellectual revolution. While certain cloistered intellectual communities would have known of Galen, Galenic doctrine was for practical purposes lost to European medicine for a millennium following the collapse of the Roman Empire in the 5th century. Galen's writings were effectively unknown in the libraries of most medieval monasteries until the cusp of the early European Renaissance. Beginning in the early 14th century, Galenic anatomical texts like *On the Use of the Parts* and *Anatomical Procedures* underwent a revival among

anatomists in European universities. First in Bologna with Mondino de'Luzzi (1275–1326) and the publication of his *Anatomica* in 1316, and then into Vesalius' time with the activities of anatomists like Jacobus Sylvius (1478–1555) and Johannes Gutiner (1510–1574) who recreated the dissections and procedures described by Galen. The point of this anatomical research was to see what Galen saw, to find what he found. Galen's authority was as yet unchallenged.

It was Vesalius who first openly questioned the accuracy of Galen's texts and even suggested that Galen himself had never dissected a human body. However, the influential Dutch anatomist represented less of a discontinuity with an ancient anatomical tradition and more of a distinct school of anatomy within an extensive field still very much dominated by Galen supporters, and those who sought to adhere to Christian doctrine. For these adherents, many of whom were at the same time trying to defend the Roman Church against Protestantism, a belief in the purity and accuracy of Galenic texts equated to the purity and accuracy of Church scripture in general. In this way, medicine and medical knowledge was very much a social discourse entrenched in religion and politics.

What was revolutionary about Vesalius was that he openly questioned the primacy of these classical texts and argued for the importance of experience, applied dissection, and observation in anatomical investigations. Galenic books ceased to represent the whole of the truth of anatomy. Even those who criticized Vesalius, like anatomist Jacobus Sylvius (1478–1555) and physician William Harvey, conceded that there were, indeed, differences between Galen's anatomical descriptions and the bodies that they themselves dissected. One creative solution to this inconsistency was to speculate that the shapes of human bodies had changed since Galen's time—that God had created humans differently in different eras. This managed to preserve the sanctity and influence of Galen's writings a bit longer, and at the same time acknowledged new anatomical observations and corrections, which could no longer be denied.

Vesalius himself found many mistakes in Galen's descriptions, and his detailed drawings, presented in his 1543 work *De Humani Corporis Fabrica* (*The Structure of the Human Body*), were

a stark departure from previous pictorial depictions of dissections that focused on representing the entire ritual of dissection, with all its participants, like the Reader who dictated Galen's instructions and observations, the dissectors dissecting the body, and the audience witnessing the spectacle.

Exhibiting much artistic skill, Vesalius's inductive naked-eye observation of the dissected body, supported by detailed true-to-nature drawings of the body and its organs, represented a stark departure from Galenic conceptions and serves as an early example of the approaches to thought and knowledge—experimentation and empiricism—that were the hallmark of Enlightenment thought and most explicitly elaborated by Francis Bacon in terms of a scientific method in 1620.

But by the 17th century, Vesalius was already outdated. While he continued to inspire as an early champion of reason and knowledge who challenged established medical authority, further additions and corrections made to anatomy after his time quickly left his actual findings and work in the archives of history. Following his death in 1564, several further developments occurred in the sphere of anatomy. For example, lacteal lymphatic vessels were discovered in the 1620s by Italian physician Gaspare Aselli (1581–1625) and the lymphatic system was more generally described in the human body by two chemists, the Swede Olaus Rudbeck (1630–1702) and the Dane Thomas Bartholin in 1650–1652.

Perhaps the most monumental anatomical achievement, symbolic of the Enlightenment era to come, was the new theory of the circulation of blood proposed by William Harvey in his *An Anatomical Disquisition on the Motion of the Heart and Blood in Animals* (1628). Whereas the precise function of the heart had been much speculated on, including the candidate theory that it acted as furnace to heat the blood, Harvey proposed that the heart, with its two ventricles, continuously pumped blood through the body using arteries and the same blood was carried to the different parts of the body. Harvey showed that it was simply impossible for the liver to continuously create the sheer volume of blood that constantly pumped and pulsated throughout the body of any given animal. As with other experimentalists or naturalists and their theories, Harvey's ideas were not

uniformly accepted across England and Europe right away. His perspective had both its supporters and critics. Predictably, the criticism focused on Harvey's deviation from Galenism. These sorts of criticisms and objections became fewer throughout the 17th century, as medicine, and natural philosophy more generally, more emphatically adopted methods of observation and induction.

The following century brought further complexity to anatomy in the form of comparative anatomy that compared the composition of different animals, including humans, in the placement and shape of organs, skeletal structure, and other features. For example, Nicholas Tulp (1593–1674), a surgeon and the mayor of Amsterdam, made some early observations on the anatomy of chimpanzees and orangutans brought from the Congo. Some of Harvey's test subjects for his theories on the circulation of the blood were also animals like eels and snails. The study of comparative anatomy and animal experimentation became an important enterprise for anatomists and natural philosophers in the 18th century. Many surgeons and physicians were skilled anatomists, but the anatomical sphere also extended into natural philosophy and early studies into animal behavior, or zoology. Georges Cuvier (1769–1832) is a worthy example of this intersection. He was both a skilled anatomist and zoologist whose work was cited and referred to by both naturalists and medical practitioners when the study of animal bodies, as an analogue to the human body, became an important avenue for research and experiment.

Classifying the Body

Surgery

Medical surgery has a peculiar history. In the present era, surgery and medicine are seen and understood to be deeply interconnected. But in the 18th century, medicine and surgery were still viewed as separate pursuits. Surgical societies and surgical colleges developed in relative isolation from long-standing anatomy- and theory-based medical schools. Beginning with medieval barber surgeons and other folk practitioners who would travel from town to town, surgery very gradually developed into a formal part of medicine.

While *proper* medicine in medieval times existed as an esoteric and philosophical pursuit for university lecturers, these medieval barber surgeons were often those to whom the common European citizen went for help. They pulled teeth, cut out ingrown toenails, helped with injuries like lacerations and broken limbs, and, owing to the ravages of syphilis, performed basic forms of rhinoplasty with skin grafts or even metal prosthetic noses.

Due to the demands of surgery and the skills required to wield a knife, many surgeons also became skilled anatomists. This was before even a rudimentary understanding of antiseptics and anesthesia, so patients often died during surgery from sepsis and shock. Postmortem examinations were commonly performed by surgeons. Anatomy as a discipline slowly drifted from the domain of formal medical doctors, closer to the domain of surgeons, which had a practical—living—component that work with cadavers in a lecture theater did not match. The anatomical knowledge that developed through the work of surgeons, combined with an increase of the practical applications of surgery to more illnesses and disorders, including lithotomies (stone removal), cataract surgeries, and herniotomies, raised the prominence of surgeons across Europe. Physicians had to understand anatomy as well, but they did not, strictly speaking, need to know those things that they did not practice. On the other hand, it became crucial for the surgeon to be a skilled anatomist at the same time as a competent physician.

Gradually, these barber surgeons began to organize themselves in guilds and professional organizations. A division began to take place between those who remained barbers practicing surgery on the side, and those who practiced surgery in a learned and focused way. The United Company of Barber Surgeons organized in London as early as 1540. Later, in 1745, this organization reformed to be the Company of Surgeons, further distancing themselves from their barber history. But the general division between English surgeons and physicians remained an important one throughout the century. However, some of the most prominent and well-known English medical authorities of the 18th century were surgeons like William Cheselden (1688–1752), Percivall Pott (1714–1788), and John Hunter (1728–1793). Cheselden worked on new methods of lithotomy

and cataract surgery. Pott not only made innovations with orthopedics and fractures but also famously established the link between scrotal cancer and the work of chimney sweeps; the first recognition of an environmental factor in the development of cancer. John Hunter, often called the *father of scientific surgery*, had a profound effect on surgical teaching in England and highlighted the importance of systematic study and surgical experimentation on animals and humans. Hunter was also a good example of a surgeon-anatomist, and his large anatomical collection of animal and human organs is housed today in the Hunterian Museum at the Royal College of Surgeons in London, England.

In France, in 1731, King Louis XIV opened the Académie Royale de Chirurgie. This institution was to mirror the surgical society in England. Two royal surgeons to the king, Charles Georges Mareschal (1658–1736) and Germain Pichault de la Martinière (1697–1783), were among its founding members. Part of this society's eventual importance was in its periodical publication, *Memoires de L'Academie Royale de Chirurgie*, which was the first periodical publication specializing in surgery. It was also in France, in part due to the many French involved conflicts in the 18th century, that surgical practices flourished as many military surgeons advanced methods of ligature of blood vessels and amputation, tendon surgery, and orthopedic surgery such as the resection of bones and joints. Famous figures of the French surgical tradition included Jean-Louis Petit (1674–1750), Henri-Francois le Dran (1685–1770), and Francois Quesnay (1694–1774), who all worked in Parisian hospitals. Like their English counterparts, these French surgeons primarily focused on the extremities and the visible illness—those maladies that were on the surface of the body or in the extremities; those parts which could be fixed in a timely manner, and without causing the patient severe pain or killing them. The abdominal cavity and the thorax still remained the purview of anatomy and dissection. It would not be until the 19th century that abdominal and thoracic surgery became possible and relatively safe for patients, and a greater understanding of the specific role of each organ, as well as their mutual interdependence, was better understood. Surgeons of the 18th century

recognized the practical limitations of their practice. Even John Hunter reportedly disliked performing surgeries precisely because of the pain that it caused patients.

Surgery, therefore, existed as a practice independent from academic, that is, theoretical, medicine for centuries. It was only toward the beginning of the 18th century that the importance of surgical practice was recognized by the public, political leaders, and medical doctors alike; it had become a vital part of medicine and a medical profession. Many practical procedures that worked to relieve pain and treat everyday problems such as broken bones, hemorrhoids, or bladder stones elevated the surgical profession and the demand for practicing surgeons. Anatomical knowledge, likewise, shifted toward the domain of the surgical profession.

Nosology and Disease Theory

Anatomical knowledge and its development were important for the entire medical domain. Yet most anatomical knowledge had come from working with corpses, and looking at an organ in the body, especially that of a cadaver, did not automatically translate into knowledge about the workings of that organ or its role in maintaining the life of the organism. Furthermore, it could say nothing about a disease affecting the organ. To understand what disease was, to differentiate it from symptoms, and to understand how the disease became clinically manifest in terms of its symptoms, required the development of ideas and theories about disease and pathology. These theories of health and disease began with the development of classification systems, not just in the sphere of medicine but within the entire field of natural philosophy of the 17th century.

The explosion of transnational trade and exploration in the 16th and 17th centuries resulted in many private collections of different objects, trinkets, plants, creatures, fossils, and even humans, from distant corners of the world. These collections, usually commissioned by wealthy individuals, eventually led to the practical need to organize and classify the objects in a coherent and logical manner. Some of these collections were modest and contained within a *Wunderkammer* (cabinet of curiosity) or they could be large and require an entire museum, such as the collection of Russian

Tsar Peter the Great, still housed at the Kunstkammer in St. Petersburg. These various collections became the object of study for many natural philosophers. The most celebrated of these early classification systems was that of the Swedish botanist, zoologist, and physician Carl Linnaeus (1707–1778), who published several major works, including *Systema Naturae* (1735). There were other classification frameworks besides that of Linnaeus, such as the geographic analysis of species by Eberhard A. W. Zimmermann (1743–1815) and George-Louis Leclerc Buffon's (1707–1788) classification studies first published in 1749. These competing ideas of classification and taxonomy were a precursor to the evolutionary theories of the 19th century. In the 17th century, the Italian *Accademia dei Lincei* (Lincean Academy) was the first to attempt to create an all-encompassing theory of order and existence for the simple honeybee in honor of their former member Cardinal Maffeo Barberini, who was then Pope Urban VIII. Interestingly, Galileo Galilei (1564–1642) was another prominent member of the Academy. These observations and classifications of the honeybee were first published in 1625 as the *Apiarium* and made use of the recently invented microscope to observe the bees in detail never before seen.

The same sort of attempts at taxonomical classification also started to appear in the medical and anatomical sphere. Perhaps the most famous 17th-century example was Sydenham's classifications of fevers. He published his observations and a classification of fevers and febrile disease in 1666 as *The Method of Curing Fevers*. His classification focused not only on the different types of fever but also grouped together different types of symptoms according to their compatibility and likeliness to occur together. Sydenham wrote down case histories and used large samples of patients to form his conclusions. While his observations on disease were still heavily reliant on humoral theory and were soon replaced by others, the general framework he pioneered was widely adopted to understand diseases and their symptoms. The same idea of disease as a combination of symptoms was still important at the end of the 18th century, even if by then, anatomy and the morbidity of specific internal organs was also considered when determining or classifying disease.

In 1731, Montpellier physician François Boissier de Sauvages (1706–1767) followed in the tradition of Sydenham to create a modernized version of a disease nosology that still primarily focused on symptoms to identify disease but implemented a system based in the categories of *classes*, *orders*, *genera*, and *species*—his classification system encompassing over 2,400 species of illnesses. The English physician William Cullen likewise worked on his own classification scheme and published it as *First Lines of the Practice of Physic* in 1778. Interestingly, Cullen doubted the utility of anatomical knowledge in diagnosis and noted that observations of internal organs and lesions were too unreliable and inconsistent to use in diagnosis and classification.

This medical tradition and theory viewed the body in a holistic sense and its vitality or health as a finite quantity. Before the late 19th century and investigations into the possible existence of specific pathogens that caused disease, the medical concept of *disease* was thought of in a more fluid manner. Life hung in a balance of health and illness and once the process of illness began, the person would gradually decline in health until their inevitable end. This process could take months or years, it could stall, and then proceed rapidly, as the disease shifted from one unpredictable form to another. In a medical climate where a large part of pathology was speculative, the main source of knowledge about the illness came from the patient and the symptoms they reported. Only the patient could feel the pain in their side or their chest, and so the external, that is visible or empirical, symptoms played a major part in a physician's determining and classifying the illness. Within this disease framework, a simple cough could turn into a fever, a fever into tuberculosis, and tuberculosis could take years to transform into cancer, signaling the end of life. Instead of separate diseases and illnesses, there was one essential *disease force*, which depleted life and which took on many different forms.

Life was likewise seen as an essential force in the vitalist tradition. Anatomist and early embryologist Johann Friedrich Wolff (1733–1794) called this force *vis essentialis* and ascribed to it all manner of functions. This vital force was why the embryo could grow into an adult animal, and it was also why a wound would heal, or why a broken

bone would grow back together. The vitalist ideas altogether became very prominent among German practitioners and naturalists. At the universities of Göttingen and Halle, figures like Wolff, Georg Ernst Stahl (1659–1734), and Johann Friedrich Blumenbach (1752–1840) embraced these vitalist principles and incorporated them into their studies of embryology, physiology, and even early histology and cell theory. These German doctors would form the intellectual tradition of *Naturalphilosophie*, which was an important school of thought in 19th-century German biology.

The major challenge to this vitalist viewpoint came from the school of mechanistic thought. This tradition was inspired by the philosophy of earlier luminaries such as René Descartes (1596–1650) and Isaac Newton (1643–1727). Within this theory, the body was seen as a machine, like a clock with gears and springs, that functioned according to physical and mathematical laws. Descartes made some observations about the mechanistic nature of the body in terms of the function of muscles and the circulation of blood in his unfinished work *L'Homme* as early as the 1630s. The first medical practitioner to be a proponent of this mechanistic theory of the human body was Hermann Boerhaave (1668–1738), a Dutch physician who worked in particular on problems of inflammation and performed some of the first analyses of tissue using a microscope. Within his mechanistic framework, the body functioned according to the laws of hydrostatic forces and pressure. Disease was described as the disequilibrium of these pressures within the body. Inflammation caused by blunt force, for example, was a build-up of excess pressure in the affected part of the body. Boerhaave's ideas were published in 1708's *Institutions of Medicine*, which became a highly influential book across Europe. Later vitalists would challenge some of Boerhaave's ideas. This included one of his own students, Albrecht von Haller (1708–1777). Haller, who was an intellectual opponent to the embryological theories of Caspar F. Wolff (1733–1794), also modified the hydrostatic vitalism of Boerhaave, instead focusing on the importance of the nervous system in the body's functioning.

Other researchers continued to pursue some of these hydrostatic mechanistic ideas. One outcome was the creation of the *blastema-exudation*

hypothesis toward the end of the century. In this hypothesis, the fluids of the body pooled in the injured or damaged areas and then congealed and solidified. This hypothesis was used by a variety of authors to explain the appearance of different pathological conditions; everything from inflammation, *a la* Boerhaave, to the appearance of ulcers, cysts, and even tumors. This perspective remained active into the next century. The downfall of many mechanistic and vitalist ideas did not occur until the mid-19th century development of cell theory. Cell division in plants was first observed by Matthias Schleiden (1804–1881) and Theodor Schwann (1810–1882) in the 1830s. These principles were then applied to the human body by pathologists, notably Johannes Peter Müller (1801–1858) and Rudolf Virchow (1821–1902). Mechanistic and vitalist perspectives were abandoned in favor of the analysis of the cell, echoing Virchow's dictum, *Omnis cellula e cellula* (All cells come from similar cells). The bacteriological revolution at the end of the 19th century brought even more stark changes to the medical and biological sphere of knowledge. As a result, medicine at the end of the 19th century looked nothing like medicine at the end of the 18th century.

Conclusion

As the preceding sections have shown, a single, unitary concept of *medicine* such as we have today did not exist before the 19th century. This concept of unified medicine came about because an assemblage of medical practitioners, anatomists, surgeons, and natural philosophers gradually built up a body of knowledge about the living body and its relation to the natural world. This process was not coordinated, and important developments could come from the unlikely of places.

As we have seen with the rejection of Galenism and humoral theory, this process was also a cultural and political matter. And was the case with the continuation of humoralism into the 18th century, the process of rejecting *old* knowledge wasn't straightforward or even always successful. Perhaps what best describes the medical achievements of the Enlightenment is the creation of new theories. Enlightenment-era medical practitioners, and other thinkers, were not able to learn to cure and effectively treat many of the same diseases and illnesses that had plagued Europe for

centuries, but they did begin to develop new ways of seeing the living body, and new ways of seeing disease and illness, that fundamentally changed the concepts of life and existence.

MEDICINE, MIDDLE AGES

Generally during the Middle Ages, extending from about 500 to 1400–1500 C.E., people in Europe still followed the concepts taught by the ancient Roman physician Galen (129–ca. 210 C.E.), whereby a body was made up of four *humors*, or fluid substances, and illnesses were a result of these not being in proper balance. Some Christian theologians in Europe argued, however, that disease was often a punishment for sin or for divine disfavor. They urged that people who were suffering should pray and endure these afflictions in much the same manner as Job had done in the Hebrew Bible. Cure came through the intervention of God, and therefore it was necessary to continue to pray. Although Gregory of Tours during the 6th century C.E. includes some of these views in his writing, they certainly predate him.

This entry explores the development of medicine during the Middle Ages in Europe, in the Arab world, and in China and the Khmer Empire (present-day Cambodia). The influence of ancient Greco-Roman sources such as Hippocrates and Galen is discussed, as is the work of early Christian physicians and the widely noted, pioneering Arab physician Avicenna, whose works were translated into Latin. The response to lethal infectious disease, chiefly the plague, or Black Death that devastated cities and entire regions in the 14th century, is described.

Beginnings and Early Practices in Europe

Some of the early Christian writers point to miracles that had been documented. Jesus of Nazareth had been involved in curing the lame, and treating the dumb, the blind, a leper, and a man who had already died. His disciple Paul of Tarsus was able to treat the father of Publius (later St. Publius) in Malta after having been shipwrecked on the island. The father had been suffering from dysentery and was cured.

A medieval manuscript in the British Library includes references to the Anglo-Saxons in England conducting some fairly crude surgery. Much of their beliefs in illness was that bleeding a wound was a cure for many ailments. This is mentioned

when a physician called Cynefrid had the task of operating on Queen Etheldrida of East Anglia in 660. The daughter of King Ine, she had a swelling under her jaw on her neck, and the doctor, according to Bede in his *Ecclesiastical History of England*, lanced the abscess. She died following this, with Bede reporting that she believed that the illness had been caused by God because of her vanity over her neck. It was reported that when her body was exhumed some 16 years later, it was found that her body was preserved and the neck wound had gone.

There are many other stories of miraculous cures in Anglo-Saxon England. After the murder of King Edward the Martyr in 978, his body was concealed in the house of a blind woman. During the night, the woman regained her sight, and when Edward was buried at Shaftesbury Abbey, there were reports of blind people coming to pray at his grave. He was subsequently declared a saint.

Although the Greeks commonly believed in washing wounds, the Roman writer Pliny the Elder suggested that the wounds could be closed using honey, and this was a practice followed by the Anglo-Saxons, who did not follow what would now be seen as basic customs of hygiene. Indeed, there seem to have been regular problems with the fouling of water, and the Saxons also often buried people inside churches and scattered the dust from these burial places on water, which would then be given to people and cattle suffering from ailments in the hope of a cure.

In the early Middle Ages, there was a major rise in the population of England, France, and many other parts of Europe. At the same time, infant mortality was high, and many babies were extensively swaddled as a way of trying to prevent rickets. During this period, what emerged as a major issue was chronic inbreeding in many villages. The Bible had an injunction against the marriage of first cousins, and this had served Christian Europe well. But with the rise in population came many second cousins marrying, thereby producing a wide range of associated health issues.

Although most people with illness were treated in their homes, usually by family members, monasteries and abbeys were emerging as places where people could seek treatment. This has its origins in the emergence of the importance of Christianity as a religion in the Roman Empire, with Pantaleon of

Nicomedia (d. ca. 305), practicing medicine among the poor, and Alexander of Tralles (525–605 C.E.) working as a skilled physician and emphasizing the powers of observation. St. Benedict of Nursia (d. 547 C.E.) entreated his monks to care for the sick, but he also instructed them to refrain from reading about medicine because of his belief in divine intervention as the only certain cure.

Some monks had the role of being herbalists, as did as the fictional Cadfael in the novels of Ellis Peters (the pen name of Edith Pargeter, 1915–1995). There is a reference to Baldwin, a French monk from the Abbey of St Denis coming to England to treat Edward the Confessor and later being made the abbot of Bury St. Edmund's. He continued to treat William I "The Conqueror," and after his death in 1098, Faricius of Abingdon, another abbot who had been trained in medicine at Salerno in Italy—the only major school of medicine in Europe at that time—took over that position as the court physician and was responsible for the treatment of many court officials. Abbot Warin of St Albans was another monk who was renowned for his skills.

It was at Salerno and then also at Montpellier in the south of France that the works of the Greek writers Hippocrates (ca. 460–ca. 360 B.C.E.) and Galen of Pergamon were translated and their references to the different bodily humors were treated deferentially. It was long recognized, however, that there were limits to medical knowledge. Since ancient times, lepers had been cast out from communities, and this continued during the Middle Ages, with leper *colonies* throughout medieval Europe. The major change was that whereas in antiquity this was regarded as an affliction that may have come about through the actions of the sufferers, in the Middle Ages many people came to pity the lepers, with some wealthy people donating money to build churches and almshouses for the lepers—prayer being seen as the main way in which they might be cured.

Medicine in the Arab World

Most treatments in medieval Europe consisted of herbal medicines and balms, as well as prayer, visits to religious shrines, and taking part in pilgrimages. Some of the herbal cures were relatively effective at

dealing with minor ailments, although the placebo effect cannot be underestimated. With the Crusades, the physicians of Western Europe came into contact with the work of Arab physicians such as Avicenna (Ibn Sina; 980–1037), whose works were translated into Latin. There was also much interaction between Moors and Christians in Spain—Morocco having emerged as a major center of learning in the Arab world although, interestingly, many of the successful practitioners there were Jewish or even Christian. Many Muslim doctors were trained in Alexandria and Baghdad.

Arab medicine has long emphasized cleanliness, and much greater hygiene than had been the case in Western Europe. This was reinforced by Islam with people washing themselves before prayer, and wealthy Muslims often leaving money for the building of bath houses. Perhaps because of the warmer climate in many parts of the Arab world, cleanliness was seen as much more essential than it was in northern Europe, and the European world learned much from the Arab world.

Avicenna was the author of *The Book of Healing* and *The Canon of Medicine*, which between them transformed much of the thinking about medicine in medieval times, with both remaining in use until the mid-17th century. Avicenna had managed to study the works of the Greeks, the Romans, and also the Persians and Indians. He had been influenced as a young man by philosophy, especially the *Metaphysics* of Aristotle. When he was 16 he had decided to turn to medicine and rapidly had much success treating patients. He then was appointed physician to Emir Nuh II which allowed him access to the important medical texts held by the court. His main new theory concerned the cause of epidemics and contagious diseases, which he felt came from bad *vapors* in the air and that hygiene was very important, as well as isolation of patients. He also was to support the view of Aristotle that tuberculosis was contagious. This was a view that had been rejected by Hippocrates and hence rejected by many people in Europe. As for the testing of medicines, he believed that the apparent success of some of these was often owing to chance, and felt it was important that all medicines should be tested on humans, because the effect it might have on an animal might be quite different.

The Plague and Its Aftermath

The work of Avicenna had much influence on some thinkers in Europe, and moves were made to try to prevent pollution of water supplies, although these were often fairly rudimentary in medieval cities, with the ever-present proximity of animals and humans in both cities and in the countryside adding to some of the problems. Moorish and Arab doctors—as well as Jewish doctors—started practicing in cities in Western Europe with some success. They often decried the heavy surgery that was still resorted to in order to treat many ailments in medieval Europe. Leg ailments were often treated by bleeding the wound and then sometimes by amputation. The lack of hygiene of some of the medical equipment presented problems of its own, and crowd scenes pictured in medieval manuscripts regularly include at least one in 10 people depicted as being crippled.

The plague had long been viewed with great fear since Roman times, and in 1346–1353, the Black Death struck Europe. Modern scholars believe that the plague arrived from Central Asia along the Silk Road and reached the Crimea in around 1343. It then traveled westward, initially brought by Genoese ships that traded in the Black Sea, and over the next 10 years it devastated communities and resulted in the deaths of approximately one third of the population of Europe and parts of the Middle East, although some modern scholars have thought that this was an underestimate, and some cities such as London, Hamburg and Bremen lost close to two thirds of their population.

The rapid spread of the plague and the vast number of people who succumbed led to many widely varying theories about its cause. The speed of transmittal of the disease meant that there was hardly any time for rational reflection, and with so many doctors and others dying, the Black Death severely tested existing medical theories. Although many recognized that this was a medical issue, it was not long before scapegoats were identified. Lepers were accused of spreading the disease, and there were also many claims that Jews had poisoned the water supplies, resulting in massacres of many Jewish communities such as those in Cologne and Mainz.

What was clear to many people, even from the start of the Black Death, was that it was caused by

contagion. The outbreak in Sicily could be dated to have occurred straight after the arrival of some Genoese galleys—Genoa having colonies in the Black Sea. The outbreak in Norway can be dated to have taken place following the arrival of a single ship at Askøy in 1349. Some cities refused to accept ships from Genoa or from affected areas, and a few isolated areas managed to escape the plague, notably the kingdom of Poland, the Basque areas of northern Spain and southern France, and curiously, some farming areas in modern-day Netherlands and Belgium, as well as the city of Milan. Some of these areas—such as Poland—escaped the plague because they were not on the major trade routes, especially by sea. In Milan, the city officials embarked on a policy of isolating any sufferers. If anybody showed any signs of infection, their house and the three next to it on either side would be closed up and walled up with the occupants inside. It was a drastic measure, but it saved the city from the massive number of deaths that destroyed so many other communities. In Prague, there was a belief that prayer in the city and a statue of the infant Jesus had protected the population.

There were major social changes following the Black Death. The loss of so many people in a large number of European and Middle Eastern cities reduced the amount of pollution and effluence, with consequent changes in people's lifestyles. It also had the result of massively reducing the tax base of many countries, leading to social upheavals such as the Peasants' Revolt in England. Many of the people who survived the plague had clearly been exposed to it and had built up a resistance to it. Therefore, while there were subsequent outbreaks of the plague over succeeding years, these were never as devastating as the Black Death. In the waning years of the Middle Ages, while changes in European thought concerning disease and illness led to continued advances in medicine, prayer still remained one of the major sources of solace for many people who were ill, or who had friends or family members suffering from ailments.

China and Southeast Asia

In China, fundamental concepts of medicine remained much the same, with the forces of Yin and Yang, seen as representing the dual nature of

the body, had to be brought into harmony for a cure to be effected. The use of herbal remedies and acupuncture continued to yield positive results, and there was a far greater body of knowledge recorded about these during the Tang and Song dynasties, thus helping doctors to develop more accurate ways of treating illness. Chinese doctors started to practice outside China itself. And Zhou Daguan (Chou Ta-kuan), a Yuan dynasty envoy in 1296–1297 to the Khmer Empire city of Angkor (in what is now Cambodia), recorded his surprise to see that lepers were not shunned by society there, as in China but lived in the community. He also noted the widely practiced custom of submerging oneself in water as a cure. This occurred following the reign of the Khmer king Jayavarman VII (1125–1218) who had transformed the state from a Hindu one to a Buddhist one, building large numbers of hospitals and hospital complexes throughout his kingdom.

MEDICINE, 19TH CENTURY

During the 19th century, Western medicine underwent significant changes. It did so by incorporating new scientific theories and concepts of disease. The century can be fairly evenly divided into thirds, denoting the end of Enlightenment medicine, or the age of systems, by the 1820s; the clinical medicine of mid-century; and the laboratory-based medicine of the late 19th century. These dates shift somewhat based on geography but are a good general shorthand. Historians generally have viewed the century in terms of medicine's transition from *traditional* to *modern*. This is a useful framework for thinking about the broad changes across the profession. In this context, *modernity* included the increasing importance of institutions like the hospital and asylum, new therapeutics, and (in many locations) greater authority of medical professionals (especially physicians). Medical theory specifically in the 19th century underwent significant change and helped shape many modern concepts from germ theory to genetics. Over the course of the century, regular or allopathic medicine became more self-consciously scientific, setting the stage for 20th-century biomedicine and medical specialization. *Alternative* medicine also grew in popularity, often appealing to older more system-based or holistic concepts of the human body. This entry is organized chronologically, according to into the three eras just described.

The Age of Systems

Working physicians at the turn of the 19th century faced a medical landscape dominated by competing ideas about the physiology of human bodies and how physiology could inform therapeutics. Despite that variation, most assumed that the nervous system, circulatory system, and other

combinations of organs regulated the functions of the human body as a whole system. Rather than view illness as an external invader, most doctors defined ailments as malfunctions of the body. When normal physiological functions struggled or failed as a result of internal or external strain, disease was the result. These physicians (like their predecessors for centuries before them) inhabited a world where disease was an ever-present feature of their lives, both the regular collection of chronic ailments, injuries, and childhood ills and, increasingly, threats from epidemic disorders. Patients demanded relief and understanding, which stemmed from the same mix of classical and Enlightenment roots as their physicians' educations. Family members, patients, and physicians alike looked to alterations in the body's immediate environment for the roots of distress and disorder. The systemic changes were considered the heart of the matter with respect to disease. Few ailments—smallpox, plague, and yellow fever were the exceptions to the rule—earned the designation of *contagious* in any modern sense of the word, and the search for specific disease-causing agents or toxins was limited. Similarly, therapeutics were general and drugs were understood in terms of their actions on the body. As late as the mid-1830s, one Ohio physician could argue confidently that medical philosophy *abhorred* a specific therapy—a single drug useful for a specific disease. Rather than a search for specific treatments for specific ailments, these physicians sought the best system with which to understand the human body.

The start of the 19th century coincided with the decline of the age of medical systems whose origins lay in antiquity and whose zenith occurred in the Enlightenment era (18th century). For over a century, Western medicine had relied on succession of medical and physiological systems to explain sickness, health, and the function of human bodies, incorporating new science into old frameworks. European medical theorists such as Georg Stahl, Hermann Boerhaave, and William Cullen each built on and critiqued the work of others to better articulate a complete understanding of what ailments existed and how they affected bodies. Some reached back to the humoral system of antiquity, while others picked up new scientific ideas from chemistry, hydrostatics, and physics to

try to explain the phenomena of life. Electricity, for example, proved a popular therapeutic agent as well as explanation for the phenomena of nerve communication and muscular contraction. The physical reality of life itself was thought by many to be a force or fluid influenced by a body's environment. Luigi Galvani's late 18th-century experiments with frog muscles—published in *De viribus electricitatis in motu musculari* (1792) and other texts—proved especially influential. Instrument-makers marketed electrical machines with explicitly medical uses during this period. Such ideas even captured the popular imagination as in Mary Shelley's novel *Frankenstein*, first published in 1818. The tale embodies the era's concern with the nature of life and how it could be manipulated by men of science in ways reminiscent of Galvani's work with frogs. However, whether they looked back to ancient Greece and Rome (Hippocrates, 460–370 B.C.E.; Galen, 129–c. 216 C.E.) or forward to the discovery of new elements or application of electricity in medicine, these theorists and innovators did have one important feature in common: they looked at the body as a unit.

We can see the practical implications of this view by considering the basic example of naming disorders. Tuberculosis will appear more than once in this entry and for good reason—it was especially prevalent during the 19th century—but we should start by thinking about the word itself. The term *tuberculosis* is a product of 19th-century medical ideas. It denotes a disease associated with a specific physical deformity; the tubercles or lesions that form in diseased lungs. Clinical medicine helped physicians connect these lesions to the signs and symptoms of disease they saw in living patients. Several decades later, bacteriology zoomed in more closely and connected the lesions with the presence of a specific microorganism: *Mycobacterium tuberculosis*. At the beginning of the century, however, medical doctors looked to the whole body of a single patient. They considered the patient's age, lifestyle, and physical environment to adjust their expectations and diagnosis. The disease that would come to be named tuberculosis was usually called *consumption*, a term evocative of what it actually did to human bodies. Those who suffered from the presence of *Mycobacterium tuberculosis* in their lungs and tissues appeared to physically diminish. The disease

consumed them in the sense that they appeared to disappear by losing weight and energy. In short, at the beginning of the 19th century, tuberculosis was a disease of the whole body, and by the end of the century it was understood to be an infection caused by a specific microorganism most closely associated with a specific bodily organ. Other 18th-century terms such as *fever* or *cholera* did not disappear but radically transformed in their meaning from a full-body disease and form of diarrhea to the sign of elevated temperature and a specific ailment caused by a specific bacterium, respectively.

Ultimately, in the age of systems, human bodies were permeable and exposed to the elements. Doctors and patients alike understood that life persisted through a careful balance of stimulation and rest, food and drink, and a healthful climate. Illness for most of these systems was interpreted as some sort of disruption of that careful balance that governed life processes. Ideas of exactly how that balancing act worked differed from practitioner to practitioner. The progress of medicine as it appeared from the perspective of 1800 was a story of one system proposed, proved wanting based on new observations and evidence, and subsequently replaced. That is how Scottish physician William Cullen understood the recent past in the preface to his medical textbook *First Lines on the Practice of Physic*, first published in 1782. Cullen and his mid-18th-century system continued to have relevance into the early decades of the 19th century. Some of this relevance came from critiques of his definitions of disease or focus on the nervous system by Cullen's former students. Related to systems was the persistent early 19th-century appeal to the work of Hippocrates, especially the works included in *Airs, Waters, Places*, which informed readers that their environments shaped their constitutions and therefore their health. From the perspective of systems and the influence of Hippocratic and Neo-Hippocratic medicine, it is easy to see how new spaces—especially those with unstable or unusual weather from a European perspective—would garner medical attention. If the comparatively minimal challenges of choosing the correct side of a hill to live on had medical consequences, then certainly the movement across continents and oceans did as well. This lasted well into the 19th century in the form of travel guides

and medical geographies like Daniel Drake's *Systematic Treatise on the Principal Disease of the Interior Valley of North America*, published in the early 1850s, which detailed the diseases found in the Mississippi Valley in geographic and environmental terms.

With this context, it is important to keep in mind that the changes in 19th-century medicine also took place during an era of imperialism. Imperial expansion in the global south directed research agendas and defined some diseases as distinctly *tropical*. The broad understanding of *warm* and *hot* climates with specific regional variation from the turn of the 19th century started to break down and form new definitions. The *tropics* and *tropical* illness formed as categories alongside widespread colonial encounters with Africa, Central and South America, and Asia in the mid-19th century. New technologies—including the ability to synthesize the malarial prophylactic quinine—allowed greater exploitation of regions previously considered unsafe or unsuited to European bodies. Medicine also played a role in othering and racializing colonial people. The customs and very bodies of colonized populations were pathologized and studied by doctors from the respective metropolises. As early as the 17th century, colonial practice and observation were a way for young physicians to make a name for themselves. While the tropics themselves became a new space for intellectual inquiry, the people of tropical spaces and their habits became subject to medical scrutiny as well. In a variety of colonial contexts, colonized subjects were recast as ill-suited to caring for their own health. While the presumed physical challenges of tropical climates were proposed as stimulating and helpful in promoting White masculinity, those same spaces were cast as detrimental to colonized populations.

The Role of the Clinic

While systems dominated the Anglophone medical world until the 1820s, the winds of change blew in France starting in the 1790s, where revolution affected medicine as well as politics. New ideas about the value of citizens and radical equality of bodies altered the way physicians were able to understand disease in their patients beyond Paris.

The clinical medicine that arose from the turmoil of the French Revolution provided a counterweight to the more holistic ideas of the past. Although observation and empiricism had been part of medicine in the previous era, clinical methods centered such observation in a different way, one where it drove theory and increasingly relied upon quantification. A new take on empirical observation and ideological commitments to the equality and *sameness* of bodies combined to shift medical analysis from the whole body and unique patient to the disease and diseased organs within a generic ailing body. This new concept was well suited to the major medical concerns of the era and the waves of epidemic disease that characterized mid-century society. Whether yellow fever, tuberculosis, or cholera, interchangeable bodies helped doctors and governments put the emphasis of medical analysis on disease rather than on individuals. Furthermore, a sense of therapeutic nihilism or pessimism set in when the techniques of the past did not meet the challenges of 19th-century healthcare.

The *clinic* of clinical medicine centered on the modern hospital. European capitals, including Paris, were home to large hospitals by the turn of the 19th century that could easily house thousands of patients organized by gender and disease type. While such institutions often had medieval roots, the separation of patients based on disease type and greater intervention of medical professionals during the early modern period slowly transformed them into something recognizable as a hospital today. However, the patients in early 19th-century hospitals in Europe and North America were almost exclusively the poor, and the hospitals were run by municipalities or religious organizations. Anyone who could afford to see a doctor at home arranged a house call. Those *worthy poor* who might appear at an institution like Philadelphia's Pennsylvania Hospital could expect treatment free of financial charge but were also expected to show gratitude and serve as living pedagogical tools for medical students. The implied exchange gave physicians and their pupils access to numerous patients and the tacit ability to test new techniques on such patients and provide basic healthcare to a subset of the poorest in the community.

At the same time, however, the role of the public in maintaining health gained renewed attention.

The metaphor of the *body politic* long predated the 19th century, reaching its most iconic image in Thomas Hobbes's *Leviathan*, first published in 1651. In the text the English philosopher framed his work stating, "by Art is created that great LEVIATHAN called a COMMON-WEALTH, or STATE . . . which is but an Artificial Man [*sic*] . . . for whose protection and defense it was intended" (Hobbes, Introduction, pp. 3–4). Nevertheless, modernity instilled a new urgency for considering the connections between the health of a people and the health of a state. Republics in particular felt the need to prove the health of the state through a demonstration of the health of its citizens. This encouraged a flurry of discussions and re-assessments of what historian George Rosen calls *social health*. The social contract between citizens and their government could be extended to include the health and safety of those citizens. Meanwhile, republican physicians like Benjamin Rush in the United States argued that good governance itself required a healthy and educated citizenry, thus placing medicine at the center of 19th-century politics and demanded public responses of healthcare. Caring for the sick and *worthy* poor as well as preventing epidemics took on new political meaning during the Age of Revolutions. The massive Parisian hospitals were an ideal location to put these ideas into practice and reframe care of the poor into care for the state itself. Rather than center individuals and their unique physiological systems as the unit of analysis, clinical physicians isolated the disease within the bodies of many citizens.

In the United States, pre-revolutionary institutions like the Pennsylvania Hospital and medical faculty in the same city were joined by similar institutions throughout the country as well as new efforts to distribute healthcare, such as the dispensary. Early 19th-century dispensaries acted as charity outpatient clinics where the poor could seek medical advice and treatment before they became sick enough to require a hospital. Doctors volunteered time or took low pay in dispensaries and hospitals in exchange for access to patient bodies. Institutions allowed practitioners to see a greater number of patients than could be seen by house call. Additionally, the hospital in particular allowed for the comparison and sorting of patients by disease type, age, and sex. In France, this sorting

and organization allowed doctors to see the sick body in a new way—not as an interconnected whole but as a unit damaged or infected in a way that could be replicated in others.

As noted earlier, tuberculosis is the classic disease to discuss in the new clinical context. Consumptive patients arrived in hospitals in staggering numbers and often terminally ill. The ailment was widespread among Europeans and North Americans during the first half of the 19th century regardless of social class. Other diseases soon followed suit. Physical manifestations of illness like the Peyer's patches of typhoid fever joined a growing number of lesions that located illness in specific parts of a generic human body. Physicians such as the Englishman Thomas Addison (1793–1860) started describing the *type* of patient associated with a specific disease and sought explanations in a specific organ system.

Another example of this shift in perspective can be seen using the example of new technology, in this case the stethoscope. French physician Rene-Theophile-Hyacinthe Laennec (1781–1826) began his discussion of auscultation, writing:

In 1816 I was consulted by a young woman presenting general symptoms of disease of the heart . . . Taking a sheaf of paper I rolled it into a very tight roll, one end of which I placed over the praecordial region, whilst I put my ear to the other. I was both surprised and gratified at being able to hear the beating of the heart with much greater clearness and directness than I had ever done before by direct application of my ear. (quoted in Bishop, 1980, p. 448)

This famous incident has been presented as the advent of the modern stethoscope in medicine. While the curling of a paper tube is a far cry from modern means of reading and understanding the sounds of internal organs, it does show the kind of innovation and change characteristic of the 19th century. After his success with the private patient, Laennec did what all good clinical physicians of his generation did and tried to apply the principle to patients in the hospital.

In addition to Laennec, a series of French clinicians took advantage of hospital practice and access to bodies to shape new ways of looking at

illness. Pierre-Charles-Alexandre Louis (1787–1872) shifted the clinical gaze to focus on signs of disease rather than symptoms. Whereas a symptom denotes how a patient feels—a key part of 18th-century physician–patient dialog—a sign does not require the same interaction or relationship with the patient. Signs are observable and often measurable changes in the body that point to a particular ailment. Think of the characteristic rash of chicken pox or the high temperatures of fever. Louis's focus on the lesions left on lungs by tuberculosis turning the vague ailment of *consumption* into something that could be readily observed—if only in dead bodies at first. Looking at bodies in aggregate allowed physicians to view disease in a new way. As noted by historians like Christopher Hamlin and Charles Rosenberg, terms like *fever* went from general disease terms to understand ill states of human bodies to signs of illness. Clinical work also saved lives. The observations of the physician Ignaz Philipp Semmelweis (1818–1865) at the Vienna General Hospital in 1848 helped explain the causes of puerperal fever—a deadly condition in postpartum mothers—from a lack of sterilized instrumentation and poor hand hygiene among physicians. Although Semmelweis faced considerable backlash for championing the necessity of rigorous sanitation, including handwashing in a disinfectant solution, an otherwise difficult-to-explain ailment started to be understood, and eventually sparked a revolution in hygiene and sanitary procedure. Two decades later, surgeon Joseph Lister honed these antiseptic methods and ideas surrounding wound healing through his work at the Royal Infirmary in Glasgow.

The 19th century ultimately gave new meaning to human bodies and *normal* human bodies. Increased interest in measurement and averages at midcentury gave rise to concepts like the body mass index while marking the slow decline of individualized humoral and environmental medicine that had dominated previous centuries. In short, the rise of the clinic as *the* location for the production of medical knowledge in the first half of the 19th century allowed for vital conceptual shifts in the meaning of disease which paved the way for the next set of innovations after midcentury.

Despite these radical changes in understanding health and healthcare, clinical medicine also cast

serious doubt on the ability of physicians to cure illness successfully. Observation and organization helped identify disease and harmful practices (like surgery with dirty instruments or excessive use of mercury-based medication) but was less helpful in efforts to find new therapeutics. In some instances, the lack of practical results led to feelings of therapeutic nihilism. Doctors in the 1830s and 1840s questioned their ability to help patients. Despite the rise of medical nihilism, or at least skepticism, by the 1830s, professional identity became increasingly solidified. In the United States, physicians formed the American Medical Association (AMA) in 1847. In previous decades, doctors had formed state and local organizations to share information, provide support, police physician qualifications, and publish medical information. A national organization, however, was something new and emerged at a time when state governments were in the process of eliminating laws governing the American profession.

The systems of the Enlightenment era failed to accurately depict the human body, but they had provided a pathway for therapeutic practice. Clinical medicine could answer questions about what specific ailments were and how they could be identified, but without the physiological or pharmacological context of a larger system the search for cures appeared stuck, or worse, pointless. During that impasse was when chemical and biological laboratories entered the conversation. Nineteenth-century physiology and bacteriology provided an additional scientific context for medicine and new therapeutic avenues that shaped care at the end of the century.

Turn to the Laboratory

By the late 19th century, the focus of Western medicine underwent another major theoretical shift as the laboratory became a site of knowledge production. The tissues-and-lesions focus of some clinical physicians shifted to the level of the cell, microbe, and chemical makeup of bodily fluids. This change was made possible by changes in medicine's allied sciences, especially chemistry. The chemical revolution at the turn of the 19th century expanded European laboratory culture, especially in Germany, and furthered the shift from doctors understanding disease as a disorder

of individual bodies to general ailments governed by the effects of toxins or microbes upon bodies. Although microorganisms had been part of scientific study since the 17th century and the advent of the microscope, the emergence of modern germ theory and association of specific microbes with specific illnesses emerged in the 19th. The search for individual diseases had opened the door for physicians to look for individual and specific causes for those ailments. Advances in laboratory technique—including dyes used to add contrast to cells under microscope examination—borrowed from chemistry, and industry accelerated these changes. Meanwhile, new vaccines could prevent specific infections. Starting with smallpox vaccination at the end of the 18th century, a new class of vaccinations for anthrax and rabies emerged from studies of bodily fluids. Far from the uniform four humors of classical medicine, the liquids that flowed and oozed through human and animal bodies were thought to contain multitudes of substances, some potentially harmful. Medicine entered the laboratory.

The chemical revolution of the 18th and early 19th centuries transformed the understanding of human and animal bodies. While clinical medicine reached its apex in Paris, others looked to chemical analysis and continued research into human physiology as an explanation for health and illness. This was especially the case in the German-speaking universities. From his appointment in Giessen, chemist Justus von Liebig (1803–1873) created the procedures and instrumentation to study the building blocks of living matter: organic chemistry. With this new framework, biochemists saw bodies as living laboratories. Liebig turned scientific attention to living bodies and started to understand life as a process created by different chemical interactions. On this view, illness disrupted those normal chemical process that took place in, around, and across cells and tissues. Meanwhile in Berlin, Johannes Peter Müller (1801–1858) busily trained the next generation of modern physiologists including Theodor Schwann (1810–1882), Hermann von Helmholtz (1821–1894), Karl Friedrich Wilhelm Ludwig (1816–1895), and Rudolf Virchow (1821–1902). These German scientists added chemistry and laboratory experimentation to the search for understanding human life. From those explorations of healthy

life processes, they also formed the theoretical background for a new medicine. Chemical techniques helped explain the function of cells, introduced new staining techniques, and were critical to the growing pharmaceutical industry, which increasingly relied upon synthetic compounds (based on naturally occurring substances) including aspirin, quinine, and opiates.

Alongside research in chemistry, biology laboratories and procedures also led to major changes in the theory and practice of medicine. In the late 19th century, the search for causal explanations of disease and modern germ theory gained new specificity. While the idea that toxins or microbes could cause illness was not new, laboratory technology and improvements to cell staining, incubation, and microscopy meant that the specific connection between pathogen and ailment could be proven analogous to the way in which signs and lesions drove clinical medicine early in the century. In France, Louis Pasteur (1822–1895) leveraged these techniques to create two groundbreaking vaccines, for anthrax in 1881 and rabies in 1885. Meanwhile, in Germany, Robert Koch (1843–1910) and his students became experts in making such connections between pathogens and specific ailments. Koch isolated two key bacteria in the early 1880s that caused tuberculosis and cholera, respectively. Their identification drew medical attention to bacteriological procedure and made the microscope as essential as the stethoscope. Koch's postulates for isolating and identifying pathogens demonstrate the strengths of the new bacteriological era. The steps both emphasize the role of the microbe in disease and the role of the laboratory in defining new diseases. The following steps were designed to allow laboratory scientists to demonstrate that microbes not only caused disease but exactly which microbes were responsible:

1. The microbe can be found in sick/dead organisms but not in healthy ones.
2. The microbe can be extracted, isolated, and grown in culture from the sick organism.
3. The microbe causes the same disease in a previously healthy organism that it did in the original sick/dead organism.
4. The process can be repeated where the same microbe can be isolated from the experimental organism.

Following this procedure, a researcher could, in theory, clearly identify the pathogen responsible for a specific ailment (if it were bacterial). The method also allowed others to replicate and verify results. A generation of *microbe hunters*, young physicians and scientists trained in bacteriology soon operated across the globe often seeking their quarry in colonial settings. Like physicians of previous centuries who participated in colonial projects to learn about new geographies and their diseases, doctors in the late 19th century viewed the *tropics* as spaces home to different microbes capable of infecting the rest of the world. New diseases defined by their causative microorganism continued to be defined in the last years of the century. So too were victor diseases, ailments like yellow fever, malaria, and typhus. Experiments that connect disease transmission to intermediary organisms now had clear chains of transmission rather than being understood as vague ills of the environment.

The laboratory revolution successfully shifted the attention of Western physicians. By the 1880s, more American students were studying in Germany than in Paris, marking the shift from clinical to laboratory medicine on an international scale. These physicians boasted the ability to work with microorganisms and maintain basic laboratory equipment. If the stethoscope and static-electrical machines had characterized earlier eras of 19th-century medicine, the age of the laboratory had its own symbols in microscopes, syringes, vaccines, and antitoxins. Returning to the example of tuberculosis, the disease took on new meaning in this new era as well. The illness known as consumption in the age of systems became the illness associated with tubercular lesions in the clinical era. Only a few decades later, the isolation of the disease-causing bacterium changed the profession's concept of the disease again. Tuberculosis of the late 19th century was a disease caused by a dreaded bacillus that lurked in unsafe bodies, thriving in the crowded and unsanitary conditions of the industrial city.

Therapeutics of course also adjusted to meet the new theories of disease, modern cell theory, and understanding of microorganisms. Researchers such as Paul Ehrlich (1854–1915) in the early 20th century could point to a future in which

anti-microbial therapy was the way forward. Rather than treating bodies and attempting to alter specific physiological processes, medicine would go right to the source and root out the pathogens.

Presenting Alternatives

Not all patients or practitioners adopted the scientific medical trends. The break from 18th-century systems did not result in a clean transition, but rather a fragmentation of medical ideas and practices. The 19th century became an era defined by alternative practices as well as increasingly scientific medicine.

Homeopathic medicine, proposed by Samuel Hahnemann (1755–1843) in 1796, was one of the earliest of the *alternative* systems and has maintained relevance into the present. Like the systems that preceded it, Hahnemann's theories stemmed from a specific relationship between the human body, disease, and nonhuman substances. At its most basic, homeopathy argues that “like cures like.” In other words, a tiny dose of a substance that causes symptoms of illness in a healthy person can be used to counteract corresponding symptoms of illness. Such substances in ultra-diluted form (sometimes up to 10,000 times) formed the basis of a 19th-century homeopath's arsenal. The practice spread from Germany to France and the United Kingdom as well as the United States. In the American context, homeopathy grew into a significant rival for *regular* or *allopathic* physicians, especially among the urban upper and middle classes. Homeopathic physicians regularly found patients and, unlike their allopathic rivals, welcomed women into their schools much earlier.

As the century progressed, other treatments came in and out of fashion, and patients mixed and matched those they found most helpful. In the second third of the century, for example, the water cure gained adherents on both sides of the Atlantic. The United States, however, proved to be an especially fertile ground for alternative medicine. By the 1840s, no state had medical licensing laws (many had been repealed), thereby allowing an open market for practice and practitioners. Alternative systems of medicine and cures not only existed but were able to create schools, and healers could legally use the term *doctor* to describe

themselves. Eclectics, homeopaths, and later in the century, chiropractors, and osteopaths all successfully competed in the open American marketplace. While their theories and therapeutics varied, most maintained some hint of the whole-body systems of previous eras of medicine.

MEDICINE, RENAISSANCE

During the Renaissance, a period in Europe of cultural, political, economic, and artistic *rebirth* that took place from the 14th to the 17th century, there were significant, sometimes dramatic, changes in society and in many fields of endeavor and study, including the theories and practice of medicine. Among the major new discoveries of the era was that of the English physician William Harvey, who published his clinical observations on the circulation of the blood, which overturned the accepted wisdom of the four bodily humors, which had been developed by Hippocrates of Cos (c. 460–c. 370 B.C.E.) and Galen of Pergamon (129–c. 200 C.E.) in ancient times.

Many of these changes and ideas arose from queries about the teachings of the church, and a greater belief in rationalism rather than leaving cures to the power of prayer, which had been argued by St. Benedict and other theologians and had since become orthodoxy. A new emphasis was placed on studying the human body, as is clearly shown in Renaissance art, and which was crucially important for medicine as far greater knowledge of

human anatomy was gained. These new ideas and theories were then able to spread through the advent of movable type and the proliferation of printed books from the 1480s onward, thereby allowing information to circulate rapidly and more freely around Europe. This entry traces the origins of Renaissance medicine in antiquity and the Middle Ages and subsequent growth of anatomical knowledge, continues with an account of the role of universities and research in the continuing development of medicine, and explores the contribution of printing and the growth of literacy in disseminating medical information. The high rates of infection and mortality caused by periodic episodes of the bubonic plague, and the transmission of other infectious diseases and the discovery of immunization are discussed, including diseases introduced by European explorers to the Americas and those brought back to Europe by returning explorers and colonists. The entry concludes with a brief account of progress in medicine outside of Europe before and during the Renaissance, and the exchanges of medical information between cultures previously isolated from one another.

Beginnings

The era of the Renaissance started in Italy about 50 years after the end of the bubonic plague, often called the *Black Death*. The devastation caused by contagious disease killed between 75 million and 200 million people in Europe between 1346 and 1353, from one third to—according to some scholars—up to two thirds of the population of the continent, as well as many people in North Africa and also the Middle East. In Florence, the birthplace of the European Renaissance, the population fell from around 115,000 in 1338 to only 50,000 in 1351. Genoa and Pisa were also devastated, as were many other cities, with Milan being one of the few cities on the Italian peninsula that escaped such devastation. Yet Florence was able to rebound and became wealthy and a center for intellectual thought and ferment.

With many people in Europe feeling, or beginning to recognize, that the resort to prayer was clearly inadequate to deal with problems such as the Black Death, medical science started to concentrate on discovering more about human anatomy. It had long been forbidden for doctors (or

indeed anybody else) to dissect human bodies, with the Greek doctor Aelius Galen and others having worked on animals, especially monkeys, to try to understand anatomy. In ancient times, some of the major advances in medicine had been made in Alexandria, Egypt, where dissections had been allowed and were carried out. Andreas Vesalius (1514–1564), a Renaissance anatomist and physician, wrote that one day when he was out looking for bones on a country highway, he came across a cadaver and used that for his studies. He was to use this and other studies as the basis for his book *On the Structure of the Human Body* which was published in Latin in 1543 and was illustrated with 277 woodcuts, which certainly helped to educate many anatomists and physicians. And certainly during the Renaissance, people such as Leonardo da Vinci and also Michelangelo, working at the Cloister of Santo Spirito in Florence (and indeed many others) were able to study the human body more closely, often being able—in the case of da Vinci—work with the corpses of felons who had been executed. And there was gradually some leeway with dissections. The Dutch artist Rembrandt, in his famous painting *The Anatomy Lesson of Dr. Tulp* (1632), shows how a doctor explained human anatomy to his students; the painting illustrates the opening up of the cadaver's left arm to display the muscles and veins more clearly.

Universities, Medical Research, and Religious Reform

The port city of Salerno in southern Italy had emerged as a major center for the study of religion in medieval times. Some of the early medieval medical experts had been trained there. Gradually the university in the city of Montpellier in France came to rival it, with the University of Paris being heavily supported by the French crown, attracting medical practitioners from England and the Low Countries. And in most major cities in Western Europe, practitioners of medicine were regulated, with barber-surgeons being commonplace. Indeed in 1540 in London, the barbers and surgeons finally came together officially and formed the Mystery and Commonalty of the Barbers and Surgeons of London, a group which later became the Royal College of Surgeons of England.

Salerno, Montpellier, and Paris, however, by no means had the monopoly on medical research. The University of Padua in the north of Italy was also fast emerging as an important center of medical learning. Niccolò Leonico (1428–1524), and the Englishman Thomas Linacre (c. 1460–1524) both trained there. Giambattista da Monte, better known as Montanus (1498–1552), was another physician associated with the University at Padua, where more bedside observations of patients were routinely made by doctors. Theophrastus Bombastus von Hohenheim, better known as Paracelsus (1493–1541) also emerged from the schools in northern Italy. Not all the prominent medical practitioners of the period, however, were trained in the north of Italy. Jean Fernel (1497–1588) who coined the term *physiology* and was the first doctor to describe the spinal canal, came from the University of Paris. Some of the early changes in medical thinking during the Renaissance came from people such as Nicolas Copernicus (1473–1543) of Poland, who was better known as a *physicist* and *astronomer*.

Another astronomer who was to have an effect on medical research was Galileo Galilei of Pisa, who, in 1592, devised the first working thermometer. Hippocrates in ancient times had emphasized the importance of body temperature but there was then no way of measuring this accurately. Galileo's thermometer was able to show changes in temperature, and differences, but it did not have a scale. It was not until 1665 that Christiaan Huygens (1629–1695) devised the centigrade scale to measure temperature, and the German physicist Gabriel Daniel Fahrenheit (1686–1736) devised another scale with made use of much smaller increments. The thermometer was to become extremely useful in studying patients as time progressed and these became more and more accurate, with Anders Celsius (1701–1744) revising the centigrade scale, which also took his name.

The ideas of Copernicus and Galileo challenged some of the major dogmas of the church and represented a new desire for scientific knowledge that took place early in the 16th century, coinciding with the Protestant Reformation, which saw the breaking of the hold of the conservatives within the Roman Catholic Church on medical ideas. The reformers Martin Luther, John Calvin, and others were challenging many of the fundamental teachings of the

church, and with the Bible being translated from Latin into English, French, German, Dutch, and other languages, religious teachings became more accessible to increasing numbers of people and previous interpretations came under question. Although prayer remained important, medical practitioners were able to experiment more and develop their own theories about the causes of ailments and how they might be cured more effectively.

Contagious Diseases, Poisons, and Remedies

The medical profession in the early Renaissance still had to deal with the many diseases and ailments that had afflicted so many people during the Middle Ages, and indeed since ancient times. There were some outbreaks of plague during the early 16th century, with one of the more devastating occurring in 1576–1577 in Venice, where some 50,000 people, around a third of the population, died. Regular outbreaks in London caused the royal court to evacuate the city, and with playhouses, including those associated with William Shakespeare, having to close for fear of the contagion spreading among crowds of people. Leprosy was still common; and smallpox was emerging as a major cause of death. In addition there were the host of common ailments such as influenza and fevers. Malaria continued to pose a major health hazard in some parts of Europe, and the Italians were the first to connect it directly with proximity to swamp lands and *bad air*—hence its name, *malaria*—the connection with mosquito bites not confirmed until the 19th century. One of the main factors that was to reduce malaria during the Renaissance was the need for more agricultural land on account of the large rise in population. This resulted in much marginal land, such as the fenlands in England, being drained, and hence the removal of many of the breeding grounds for mosquitoes.

Poisons were also becoming easier to access, and the prominent Borgia family in Rome became notorious for accusations of poisoning their political rivals and enemies. Food and drink tasters were employed by many noble families, and the Roman Catholic Cardinal John Fisher, the bishop of Rochester, was victim of an attempted poisoning.

His cook, Richard Rice, became, in 1531, the first person in England to be executed by being boiled alive, in an effort to make the punishment a deterrent to anyone else planning to use poison. Antidotes to some poisons were developed, and it was rumored that some Italian political figures daily took a small dose of some poisons to make themselves immune should there be an attempt to kill them. One problem that continued to be faced was also the use of certain poisons in small doses for medical reasons and people accidentally dying when taking, or having been prescribed, the wrong dosage.

Emerging in Europe during this period were newly introduced diseases, of which the most important was syphilis, brought back by sailors in the crew of the ships of Christopher Columbus when they returned from the New World. It spread quickly around the ports of Europe where it became known as the Venetian disease, the French disease, or by any name which indicated that it was passed on by foreigners. Spanish soldiers fighting to defend Naples against the French troops of King Charles VIII spread it among the Neapolitans, and the French soldiers after their occupation of the city in 1495 quickly either succumbed to the disease or took it with them as they retreated through Italy back to France. Gonorrhea also emerged as another important sexually transmitted disease. Its cause, and indeed that of syphilis, was known at the time, with gonorrhea being treated by an injection of mercury. A syringe was recovered by archaeologists from the *Mary Rose*, the Tudor warship that famously sank in the Solent, the straits between the Isle of Wight and the English mainland in 1545, showing the method of injection at the time.

The transmission of disease following the discoveries of Columbus was not all one-way. Many European diseases were taken to the Americas by sailors and conquistadors. Large numbers of indigenous Americans very quickly succumbed to influenza and smallpox—the latter sometimes being deliberately spread. There were documented instances of blankets and other items infected with smallpox or from people who had died of the disease being given to indigenous peoples in North America, showing clear evidence of the Europeans' knowledge of the effects from coming into contact with items from people who had a contagious disease.

The Europeans are also believed to have taken malaria to the Americas, and this was also devastating for many indigenous peoples there. Yet it was also in the Americas that a possible cure for malaria was discovered. It was found that treatment with the cinchona bark, in a powdered form, was able to cure sufferers from malaria. The curative properties of the bark were known from the 1560s and 1570s, but the rarity of the trees led to a massive demand exceeding supply and the treatment becoming very expensive.

It was the Jesuit Brother Agostino Salumbrino (1561–1642), a former apothecary, who found that the Quechua people in modern-day Peru used to chew the bark of a particular tree to relax the muscles and prevent shivering in low temperatures. As shivering was one of the symptoms of some people with malaria, he investigated further. There is a popular tradition that the bark was given to the Countess of Chinchón, the wife of the Luis Jerónimo de Cabrera, Spanish Viceroy of Peru in 1638, curing her, with the story entering into local folklore. It was Salumbrino who labeled the tree as the *fever tree*, and because of his membership in the Society of Jesus, the bark became known as *Jesuit's bark*. It was sold in Europe, and there were many attempts to cultivate cinchona trees in Europe. Superstition was never far from the surface in medical treatment and there were claims that Oliver Cromwell, who grew up near the Fenlands and might have been suffering from malaria for much of his life, refused treatment with the bark because of its association with the Jesuits. King Charles II took the treatment, but in secrecy.

War Injuries and Trauma

Injuries in battle had been commonplace since the first fighting in prehistoric times. However, during the Renaissance, the development of firearms led to changes in surgery, with the French barber surgeon Ambroise Paré (c. 1510–1590) writing his famous treatise in French, *The Method of Treatment for Wounds Caused by Firearms* (1545). A previous writer, Giovanni da Vigo (1460–1525), had suggested that people suffering from bullet injuries should have their wounds treated with hot oil to cleanse the injury. Paré, however, was not convinced by this, and his empirical research on

soldiers after a battle was able to demonstrate that those who were not treated with oil made a far better recovery than those who were. His book established Paré as a pioneer in surgery and on the treatment of battlefield wounds.

There were many religious wars in Europe during the 16th century, and during the first half of the 17th century, much of Europe was devastated by the Thirty Years' War (1618–1648) with England, Scotland, and Ireland badly affected by the Civil Wars of the 1640s. This resulted in large numbers of injuries from fighting, but also a breakdown in law and order, attacks by marauders and deserters, and the spread of diseases. Some saw these wars and devastation as divine judgments on society for its ills. But at the same time, it was a period of much change in medical thinking.

Harvey and the Discovery of Circulation of the Blood

As mentioned earlier in this entry, the most important new theory that emerged was from the English physician William Harvey (1578–1657). Born in England, he had trained at the University of Padua, having become a doctor of medicine in 1602, aged 24. Returning to England, he treated patients at St. Bartholomew's Hospital in London, the oldest hospital in Europe, having originally been founded in 1123 and still occupying its original site. Harvey had been influenced by the work of Michael Servetus (1511–1553), who had studied the blood and the lungs, with Matteo Realdo Colombo (c. 1516–1559) embarking on similar work. Andrea Cesalpino (1519–1603) had actually made references to the circulation of the blood; Harvey, working as court physician to King James I and then King Charles I, later embarked on his own study of blood. This was published in 1628 as *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (*An Anatomical Exercise on the Motion of the Heart and Blood in Living Beings*) and his theory, since proven, was about the circulation of the blood around the body, transforming people's understanding of physiology. Initially there was much controversy, with some doctors ignoring his work, and others trying to disprove it as it questioned—and contradicted—the thoughts of Hippocrates and Galen, which had dominated

medical thinking since ancient times. Robert Fludd (1574–1637) and others, however, came to the defense of Harvey, whose work has been acclaimed as being of the greatest importance in the study of physiology.

Further Outbreaks of the Plague

Around the time that Harvey was working on his treatise, there were more outbreaks of the plague. Indeed there had been quite a number during the 16th century and the early 17th century. About a tenth of the population of Amsterdam died in the plague in 1623–1625, and around a million French people died in an epidemic in 1628–1631. The Italian plague of 1629–1631 raged through northern Italy and resulted in the deaths of nearly 300,000 people, especially in Lombardy and around Venice. It was believed to have been spread by German and French soldiers when they took Mantua, and then by Venetian troops, infected with the disease, retreating north. Milan, having been spared the Black Death, lost some 60,000 people, nearly half of the city's population.

The outbreak of the Great Plague in London in 1665 brought back some of the fears of earlier, smaller outbreaks, and some historical comparisons with the Black Death and the devastation of that outbreak more than 300 years earlier, and thoughts of it being divine intervention after 5 years of what Puritans had seen as licentiousness following the restoration of the monarchy in 1660. By 1665, the connection between the plague and rats was noticed, and as a result with the outbreak in 1665, great efforts were made to kill rats, which unfortunately had the effect of the fleas (which actually carried the disease and used the rats as hosts) jumping onto humans and using them as hosts, thereby spreading the disease further. There is also the famous story of the village of Eyam in central England. Some damp clothes had arrived from London and brought with them fleas, with some of the locals quickly succumbing to the plague. Rev William Mompesson of the Church of England, and the Puritan minister Thomas Stanley, both decided to quarantine the village and prevent people leaving and spreading the plague elsewhere. Out of the original population of 350, only 83 survived the 14

months of the plague—although some writers claim that the population of the parish was actually around 800, with just over half surviving. Certainly the villagers were brave and prevented the spread of the disease, but also if they had actually evacuated the village early on, and left it empty for several days, the fleas with no host would have died, and most of the villagers would have survived.

Developments Outside Europe

Outside Europe there were also gradual changes in medical thinking. Smallpox was a major cause of death among Europeans, and this continued to be the case until a smallpox inoculation was developed by the English doctor Edward Jenner in 1796. A study of ancient texts shows, however, that Western medical theories were a long way behind those in Asia, with the possibility that some form of inoculation was being used in India from as early as 1000 B.C.E., and there were certainly inoculations against the disease in China from the end of the 10th century, gradually becoming common by the 16th century.

There was also a division of thought in China between six emerging and different—but by no means indistinct—schools of medical theory. There was still much interest in the complementary principles of Yin and Yang, with doctors feeling that illnesses came from an imbalance between these. Some, known as the *Wen-pou* doctors felt that there was too much emphasis on the *yang*, and that patients should be treated with ginseng or aconite. And there was another school that sought to bring all the presumed five elements and the six vapors into some kind of harmony, which would then cure ailments. A radical group emerged and started to urge for much more drastic medication. This saw men like the physician Chun Szi-sung prescribing arsenic to treat venereal diseases and being remarkably successful. Some conservatives insisted on sticking to the classical medical studies—some of which were several thousand years old. They claimed that there should be no deviations from these works. There was a sixth group, which came to be known as the Eclectic physicians who used a variety of the techniques of the other groups and were adaptable to change.

Acupuncture, developed in China, spread to Korea and Japan, and some of the Jesuit missionaries and others visiting China brought back some knowledge of it with them to Europe. A Dutch surgeon, Jacob de Bondt (1592–1631), described the practice of acupuncture in Japan and Java in his book *De Medicina Indorum*, published in four volumes. In it he describes beriberi for the first time, and also the dysentery epidemic which had broken out on Java in 1628. A colleague, Willem Piso, expanded the work, and a new edition was published in 1658 with Piso contributing a large section on medical treatments in the Americas.

Hermann Buschoff, a Dutch priest working in Batavia (modern-day Jakarta, Indonesia) wrote in 1674 about moxibustion, whereby *moxa* from a dried mugwort was injected into the skin by acupuncture. And in 1682, the Dutch physician Willem ten Rhijne (1647–1700), working in Nagasaki, Japan, described acupuncture for the first time in detail in Europe in his book *Dissertatio de Arthritide: Mantissa Schematica: De Acupunctura: Et Orationes Tres*. He also made a study of leprosy based on his experiences in Asia.

In addition to describing Chinese medical techniques, Western writers also took to China some European medical techniques; many of these were able to be reconciled with existing Chinese herbal treatments and surgical techniques. Herbal treatments continued to be used in China, along with acupuncture. Both were based on detailed records as much as a thousand years old, with a very wide range of treatments being tried and tested. Because of these traditions, there were not that many changes between Chinese medicine and medical techniques from the Middle Ages and those of the Renaissance.

In the Middle East, there were also many similarities between treatment in the medieval period and those used in the Renaissance. Within the Ottoman Empire, Constantinople (now Istanbul, Turkey) was affected by the plagues, as were other cities. This led to various attempts to try to clean up the city, with the plague thought to have arisen from poor living conditions. The link to rats—also established in Europe—was known, but not the connection between fleas and the actual transmission of the plague. However, generally apart from these epidemics, health services around the Ottoman Empire were reasonably good, with

hygiene emphasized by doctors and as a part of the Muslim religion. Holy men helped talk through medical problems with people, administering medicines, as did an increasing number of processional doctors. Herbs were used for some treatments, with the smoking of herbs being recommended to relieve congestion in the chest, with rhubarb used as a laxative, and anise seed to help digestion.

More problematic were psychological illnesses, with some of the treatments involving the pouring of lead. For this, lead was melted in a spoon and then poured into a bowl of cold water. The patient then had to drink some of the water, which was believed to have a therapeutic effect. Another group of doctors were trained in the setting of bones, and used forms and massage in dealing with people suffering from misshapen limbs. Surgery in the Islamic world was a well-practiced art, with surgeons in North Africa and Anatolia known for their skills, which were believed to exceed those of many Europeans. The higher success rate was probably based on the higher hygienic standards that were followed in the Middle East more than in many parts of Europe.

MENTAL MODELS

Mental models serve to explain patterns of thought that help people understand their world and the logic for their decisions. A model reproduces the structure of a phenomenon, illustrating the

integration of its crucial features. A scale model might reduce something otherwise too large to study, such as the solar system, or enlarge something too small, such as the DNA helix. A step removed from building a physical model is to represent it using symbolic language for the causal relationships within the structure of the entity. The abstract representation is a conceptual framework that serves as a template for organizing related knowledge. *Model building* refers to an intellectual exercise for constructing such a representation. The following semi-chronological account tracks the evolution of the concept as well as illustrating the connection to whole–part considerations in model building.

Origins and Development

All theories featuring mental models share the legacy of the ancient Greek philosopher Aristotle (385–322 B.C.E.), who noted in the tenth chapter of *Metaphysics* that “The whole is more than the sum of its parts.” Kurt Koffka (1886–1941), one of the German phenomenologists who launched Gestalt psychology, insisted on a more nuanced meaning by saying “whole is something else than the sum of its parts, because summing up is a meaningless procedure, whereas the whole–part relationship is meaningful.” This can be contrasted with behaviorist studies of discrete psychological phenomena: The shift was one of perspective and scale from the molecular to the contextual, from the mechanistic to the organic, from inequitable differences to meaningful commonalities, or as Buckminster Fuller labeled it, *synergy*. The perspective changes from a two-dimensional cause and effect sequence to a three-dimensional structure of multiple simultaneous influences. There is a further emphasis on the active and proactive compared to the passive and reactive. This family of theories is therefore dynamic, attending to the interactions and responsive processes in what are seen as functioning systems. The economist and political theorist Karl Marx (1818–1883) introduced the term *interdependence* in the Communist Manifesto as part of the argument against social alienation and to emphasize the importance of establishing cooperation among autonomous individuals. Kurt Lewin (1890–1947) formulated an equation to represent this contextual influence: $B = f(P, E)$, that is,

Behavior is a Function of the Person in the Environment, as part of his *field theory* that required a present context in order to understand the individual. Lewin is also credited with the term *group dynamics*, which remains central to much organizational theory, as does Morton Deutsch's model of *conflict resolution*. Urie Bronfenbrenner (1917–2005) developed an *ecological systems theory* incorporating five environmental systems, expanding outward from the individual's immediate sensory context through micro- to macrosystems.

Principles of Mental Models Theory

An important principle in mental models theory is that each individual will construct meaningful models for understanding their world and that the individual mental models will always feature some variation between people. Further inconsistency may be noted within the individual who will have developed innumerable such models for concepts. Contrary information creates *cognitive dissonance*, upsetting the equilibrium described by the old mental model. This becomes a problem to be solved, often with a domino effect because the component parts are interdependent and dynamic. Mental models theory holds that individuals are continually constructing and revising these cognitive maps. Once formed, the mental models explain the persistence of false beliefs due to a preference for a familiar orientation; that is, a reliance on what one has assumed is a reliable map. Aligning one's unique set of mental models is the hallmark of maturity and integrity, while a fragmented capacity to understand or act is associated with mental instability if not insanity. Philosophically, this might be termed an existential crisis, revealing the close alignment of mental models theory with existentialism; in other words, the focus of understanding reality in terms of one's experienced existence rather than some preordained destiny or divine purpose. Mental models as a term is thus chiefly associated with cognitive science; that is, psychologies of perception, representation, and learning.

There are multiple theories to explain the process of finding a logically consistent balance among many separate concepts. First, according to the Swiss developmental psychologist Jean Piaget (1896–1980), *equilibration* is a biological necessity; in other words, the internal mental structures

must be aligned and realigned to maintain balance amid multiple, overlapping concepts. Piaget proposed two possible responses: assimilation, or the addition of new information into an existing framework, and accommodation, or the adjustment of the framework to align with the new information. Second, according to *cybernetics* theory, feedback occurs, which prompts adjustment in one's mental model. Third, Phillip Johnson-Laird proposed a unified theory of reasoning that uses mental models to integrate three patterns of thinking, namely the inductive, the deductive, and the probabilistic—and their many products of understanding, such as inductions, explanations, estimates of probabilities, and informal algorithms. He explained that the mind represents each possibility in a separate mental model and then is able to infer what remains constant among all of them.

Executive Functions, Worldviews, and Statistics

The ability to analyze a complex concept in order to extract its essential components and functions is considered a higher level of thinking than to merely recall information, as is the ability to create something representing the cohesive whole. These *executive functions* are used to understand the world and to construct internal mental structures that can be further generalized to novel scenarios. This process may seem intuitive if prompted by extensive experience that allows patterns to become predictable, but it is nonetheless hard work. For this reason, once an individual has formed a mental model, it becomes a reliable tool for further understanding, and one is reluctant to *reinvent the wheel*, or in colloquial language, “Don't fix what ain't broke.” It is therefore reasonable that false beliefs persist in the face of contrary information because so much effort has already been invested in the incumbent conceptualization. Studies in adult development have found the increasing tendency to reduce details to gross generalizations, especially after age 55, an important factor to consider social culture as the human population lives longer. As technology has increased along with competition for attention, mental models theory is helpful for explaining the difficulty of reasoning while monitoring stimuli. Mental models are useful for researchers to study which distractions most impair higher level

reasoning. Because verbal stimulation appears to interrupt reasoning to a greater degree than simple rhythmic auditory stimulation, there is more support for the idea that mental models do not merely represent an understanding of reality in symbolic form but are actually the language of understanding. The noted linguist Noam Chomsky has argued that language is not just a tool but the actual mechanism of thought. Computer languages try to reconstruct mental models in order to simulate human reasoning.

Many names—for example schema, conceptual framework, belief system, worldview, mindset, theoretical orientation, and even philosophy—have been used interchangeably to suggest an integration of related ideas into a cohesive and functioning whole that represents reality. The *individual psychology* of the Austrian psychoanalyst Alfred Adler (1870–1937) suggested that people develop worldviews that serve as templates for finding sense in a random world. Martin Seligman promoted *positive psychology*, that is, the study of human potential instead of the abnormal and pathological, which addressed three types of happiness: (1) pleasure and gratification, (2) embodiment of strengths and virtues, and (3) meaning and purpose. While the first may be seen as an emotional response and the second a matter of identity and self-efficacy, the third suggests a conceptual framework about life wherein one influences one's own perspective. Thus mental models are a useful tool for appreciating the complexity of living in a complex world. The sophistication of modern statistical packages is due to the capacity to calculate correspondence among many variables; the quality of a study rests on its capacity to fully describe the relationships among them and to identify rival hypothesis and confounding influences that complicate the usefulness of the findings.

Mental Models in Communication and Teaching

Efforts to organize ideas are not new. The great rhetorical traditions feature coherent, logical arguments; a disorganized rant is less likely to persuade. Master communicators, whether in the classroom or the pulpit or on a campaign trail, have long used figurative language to help explain concepts and inspire action. By use of analogy or

metaphor, one is led to transfer an understanding of some aspect of a familiar phenomena to a novel phenomena. The underlying structure is thus abstracted and a sense of truth may be developed to predict and explain reality. To use a travel metaphor, the mind can more easily navigate the crowded landscape of phenomena by using a cognitive map for orientation. Poetry is powerful in its capacity to envelop the listener in a representation of combined sensory perception. Aphorisms, parables, and allegorical stories become clichés within a cultural literacy because of their enduring value to make efficient sense out of the counterintuitive or confusing.

We are witnessing shared mental models emerge in response to news as varied as the abduction of Nigerian school girls (#bringbackourgirls) or the fear of climate change or the use of Common Core math standards. Finding out others' mental models helps predict compatibility of purpose and method, and thus mental models are a useful means to discover the degree of alignment among a group of people who must collaborate. Mental models are thus useful at a corporate level as well. Schools of thought are more advanced articulations of shared beliefs. These conceptual frameworks, for example, political ideologies, fitness regimes, pedagogical methods, religious doctrines, military strategies, and artistic genres, in turn provide a focus for affiliations as well as feuds. Many debates reveal another dimension, the mental model of corporate effectiveness. Team performance has been found to correlate with *team mental models* (TMMs). Teams in any domain, such as sports or business, work to achieve outcomes requiring complex decisions. The profiles of shared cognitions are further distinguished between common knowledge that varies little between teams and team-specific knowledge. The principle of *equifinality* explains why the specific knowledge is not as significant as the degree to which that knowledge is shared: Several different TMMs in the same domain may be effective. Thus, the production of intended outcomes is informed by measures of agreement. This recent line of organizational research relies on increasingly sophisticated multivariate statistical analyses to describe the agreement within teams as well as between teams, resulting in new formulas to reduce data and indices to summarize shared cognitions. The objective

of establishing team cohesiveness serves the ultimate goal of team effectiveness. Similarly, socializing individuals to function collaboratively is an important part of school curricula because research has found that people who lose their jobs suffer not from ignorance or incompetence so much as incompatibility. Disagreements often hinge on dispositions; that is, the profile of beliefs, attitudes, and values that justify decisions made and roles played. Organizations therefore try to inspire loyalty and consistent performance by providing guidelines in the form of mission statements, mantras, strategies, and dogmas that are memorable for their simplicity. Logos and branding are key, but they serve a more nuanced purpose if they symbolize the structure of the model instead of merely providing a distinctive motif.

The theory of mental models is revealed in the use of visual strategies to improve teaching and learning. As a tool, mental models are used to influence comprehension for a great range of purposes, such as teaching the causes of a war or the function of the circulatory system, or for promoting strategic communication and decisive action. *Advance organizers* present mental models that highlight crucial relationships of elements before the component parts are understood fully. Extensive educational research supports their use and in turn inspires the development of more theories of learning. The reverse process can be seen in a *concept map*, which is constructed in order to show the relation of component parts to the main concept. This can be used as an assessment tool to determine whether a concept has been learned, or as a brainstorming tool to help a team collect all significant issues for consideration related to the team's goal. A concept map may also be used as a writing tool to promote cohesive thought, often called a *word web*.

Mental models are compatible with many practical applications in education. Gardner's multiple intelligence theory posits that a concept can be understood in several ways. From a mental model perspective, multiple intelligences can be seen as different ways in which to perceive and organize one's understanding. The use of manipulatives to learn mathematical concepts is now standard practice. Teacher candidates are cautioned to consider the great range of student differences and thus expected to use a variety of methods in response to student characteristics. Assessment instruments are

no longer limited to selected response items with one right answer. Rather, teachers are expected to use constructed response items, such as reflective essays or projective drawings or concept maps, to find out what and how well students have learned the target concepts. Teachers are also cautioned to consider the cultural influence of the models they use, for instance, the Mercator projection of the three-dimensional globe to a two-dimensional map distorts the relative size of the dominant, Western areas, which in turn may be regarded as a disservice to underrepresented societies. Finally, schools are now held responsible for interrupting students' negative mental models of exclusion and privilege, in part because antisocial behavior is influenced by prejudice. Thus, when teachers are interviewed, they are asked to provide a statement of their beliefs about teaching and learning; that is, they must articulate their own mental model of their role in the profession.

METAPHYSICS

Metaphysics is the study of the fundamental nature of reality. It is concerned with questions of existence and its nature. Ontology, the study of what exists, is a branch of metaphysics. The subject is extremely broad and as old as philosophy itself, so a comprehensive survey of the subject and its history is beyond the scope of this entry. Instead, following some brief background remarks, the entry will focus on giving a detailed example of one traditional metaphysical debate that serves both to illustrate the types of concern that metaphysicians deal with, and to give a sense of how the subject's history connects with its modern form. Following some further remarks about the fall of metaphysics in the 17th century and its revival in the latter half of the 20th century, this essay concludes with a brief overview of the influence of metaphysics in other areas of philosophical inquiry and in science.

Background

Although Plato and the Presocratics present metaphysical arguments, the first work to bear the title *metaphysics* is a selection of writings by Aristotle, written in the 4th century B.C.E. Aristotle described the subject matter of these writings as *first philosophy* but did not himself use the term *metaphysics*. This title was bestowed by Andronicus of Rhodes, the editor of Aristotle's works who collected the writings together in the 1st century C.E. At that time a significant part of one's philosophical education would have consisted in a

close reading Aristotle's works, and that Andronicus called the selection *metaphysics* reflects the fact that the writings contained therein were to be studied after (i.e., temporally) Aristotle's work on nature (*ta phusika*). So, although the etymology of the term *metaphysics* suggests that its subject matter is *that which goes beyond physics*, this is a misnomer. Even knowing this, however, one might still be puzzled about the distinction between metaphysics and physics. The reason is that one might reasonably describe physicists themselves as enquiring into the fundamental nature of reality. The methods employed by physicists differ markedly from those employed by metaphysicians, however, and they deal with questions at different levels of abstraction. Physicists are primarily concerned with the existence of particular physical particles, properties, and laws. Metaphysicians, by contrast, are more concerned with what kinds of entities physical particles, properties, and laws *are*, and with whether any of them is (or are) more fundamental than the rest. And while physicists primarily employ empirical methods to establish their claims, metaphysicians primarily employ *a priori* methods to establish theirs. However, as the last section of this entry will outline, the relationship between metaphysics and physics (and science more generally) is nonetheless a more intimate one than this might suggest.

Examples of questions that metaphysicians have sought to answer include (1) What is the relationship between the mind/mental properties and the body/physical properties? Are they distinct, or identical? (2) What is time? Does it flow? Do the past and future exist as the present does? Is time travel possible? (3) How is persistence over time possible? How can one and the same thing have different properties at different times? (4) Do we have free will? Is determinism compatible with our having it? (5) What is causation? Do causes necessitate their effects? (6) Is there a God? If so, what is His nature? (7) Could there have been nothing at all? More generally, which events are possible, and which impossible, and what makes them so? (8) Do abstract objects such as numbers exist? Are mathematical truths mind-dependent or mind-independent? (9) Do the fundamental entities posited by science, such as electrons and quarks, exist? Or are they just useful fictions? (10) What kinds of entities are objects and properties,

and what is the relation between each object and the properties it possesses? Is either more fundamental than the other?

Each set of questions has generated a substantial literature (both historical and contemporary) that continues to grow, and so it is not possible to cover each in detail here. In lieu of that, in order to give the reader a better grasp of the kinds of issues that are dealt with in contemporary metaphysics, and how they connect with the history of the subject, the last set of questions is examined in more detail in the next section. (Some of the other questions are discussed in other entries in this encyclopedia, and interested readers are encouraged to consult the cross-references in addition to the further readings for more details.)

Objects and Properties

The term *object* (or *substance*, or *particular*) is used by metaphysicians to pick out individual things that bear properties, but that are not themselves properties (this latter qualification is needed because properties can themselves have higher order properties). Everyday examples of objects include people, cars, tables, and houses. But larger physical items such as planets and stars, and smaller physical items such as atoms and electrons, are also objects. In addition, abstract entities like numbers (if such there be) are objects. The term *property* (or *quality*, or *attribute*) is used to pick out ways that objects (and properties themselves) can be. Everyday examples of properties are those possessed by everyday objects. People can have the property of *being tall*, cars of *being fast*, tables of *being brown*, and houses of *being semidetached*. But all objects, it seems, bear properties of some sort. Every star and atom, for example, has a certain mass, every electron is negatively charged, and every (natural) number is either odd or even. This raises the question: What is the relationship between an object and its properties?

Realists maintain that objects and properties are distinct but equally fundamental kinds of entity. An object possesses a property, on this view, by bearing some kind of relation to it. An important motivation for *realism* is the felt need to explain how two objects can be the same in certain respects. Consider: This apple is red, and

so is that table, so the apple and the table are identical in that respect. An appeal to the existence of properties is supposed to offer a way to explain how this can be. Views of this kind predominated from ancient times until the early medieval period, when *nominalism* (discussed in the next paragraph) began to gain ground. Objects are generally viewed by realists as being unitary nonrepeatable entities that exist by having parts that occupy single spatiotemporal regions. But there is less agreement regarding properties. The two main traditional realist conceptions of properties are those of Plato and Aristotle respectively. Plato's view is that properties are immutable entities called *Forms* that exist in a supersensible realm. Objects possess properties on this view by standing in a special *participation* relation to them. Aristotle's view (on the most common interpretation) is that properties are entities called *universals* that exist wholly and immanently in each object that possesses them. The Platonic view came under heavy criticism in the medieval period and had all but disappeared before the Renaissance, but Aristotle's view has proved more durable, and has survived until the present day. Currently, the most prominent modern defender of the Aristotelian view is perhaps the Australian philosopher David Armstrong. On Armstrong's version of realism, universals are nonspatial parts of the objects that possesses them. This account has the advantage of being able to explain in a particularly simple way how two objects can be the same in certain respects; they can be so simply by having a numerically identical nonspatial part in common. It is worth noting, however, that on Armstrong's view it is only those universals that correspond to fundamental physical properties that exist, and all other resemblances are explained in terms of the sharing of these universals.

In contrast to realists, nominalists hold that objects are the only fundamental entities that there are. They either deny the (mind-independent) existence of properties altogether, or explain how their existence is parasitic upon the existence of objects. The 4th-century Roman philosopher Boethius was the first to discuss this view in any detail, but it was in the period between the 11th and 16th centuries that the view gained widespread support. Important defenders of the view

in this period include Peter Abelard, Thomas Aquinas, and William of Ockham. The latter's view is that properties exist only in the mind as concepts that apply to many things at once. Although similar nominalist views have been expressed by major historical philosophers since this period, Ockham's work serves as the pinnacle of historical thought on the position. Only in recent times has it become clear that nominalist positions are available that allow properties to be mind-independent (nonfundamental) entities. According to one of the most popular views of this kind, properties are nothing but sets of objects. So, for example, the property of *being brown* is just the set of all objects (in this case physical objects) that are brown. This view is most closely associated with the 20th-century American philosophers Willard van Orme Quine and David Lewis. Both reject the contention that we must admit the existence of properties so as to explain how two things can be the same in certain respects. Instead they maintain that facts of this sort are basic facts that require no further explanation. This, combined with their adherence to a methodological principle known as *Ockham's razor* (viz. that we should avoid a commitment to additional kinds of entity wherever possible), is a major motivation for their nominalist position.

Bundle theory, a view that has only come to prominence in recent times, reverses the order of dependence invoked by nominalists. According to bundle theorists, properties are the fundamental entities, and objects are nothing more than com-present collections of them, and so parasitic upon them for their existence. This progenitor of this view is the 18th-century Scottish philosopher David Hume who held that the self is nothing but a bundle of perceptions. Those who adopt bundle theory are generally motivated by an apparent epistemological difficulty that surrounds the concept of an object: If an object is a bearer of properties but not itself a property, then it is difficult to see how we can form any positive conception of what an object is, for if we try to conceive of any object in abstraction from its properties, there is nothing remaining for us to form a conception of. For those with empiricist leanings, this consideration casts considerable doubt on the coherence of the concept of an object. Indeed, it was John Locke, a committed empiricist, who first noted the

difficulty in the 17th century. Locke suggests, though, that despite this difficulty, we must retain a commitment to objects in our ontology in order to explain what ties together properties into the distinct clusters of them that we face in experience. He suggests, in other words, that objects are needed to serve as the things in which properties inhere. Bundle theorists, however, believe that they can explain everything that needs explaining here, while avoiding a commitment to objects altogether, by maintaining that properties can be bound together into bundles by standing in a mutual relation of compresence.

Bundle theory is, at least *prima facie*, compatible with the view that properties are Aristotelian universals. But despite there being some notable defenders of just such a view (e.g., Bertrand Russell in the 1940s) most have been convinced that it is untenable by the following argument: (1) If objects are nothing but bundles of Aristotelian universals, then it is impossible to have two exactly similar objects (for *they* would be bundles of numerically identical universals, and so *they* would in fact be one and the same bundle). (2) But it is possible to have two exactly similar objects. C. So, objects are not bundles of Aristotelian universals. This argument was put forward forcefully by the British-American philosopher Max Black in 1952. In the following year another American philosopher, Donald Williams, published a highly influential defense of bundle theory that avoids this problem by conceiving of properties as being, like objects, unitary nonrepeatable entities that are identical with their instances. Williams coined the term *trope* for entities of this sort, and since then the literature on bundle theory has been dominated by the trope variant of the view. Many of the reasons put forward for believing that properties are tropes, however, do not involve a commitment to bundle theory, and many who reject the view have found a place for tropes alongside objects, instead of universals, in their ontology of fundamental entities.

The Fall and Rise of Metaphysics

The foregoing description of the debate surrounding objects and properties is necessarily far from exhaustive. For example, it makes no mention of those who admit further fundamental entities into

their ontology (e.g., Jonathan Lowe who holds that there are four kinds of fundamental entity). Nor does it mention those who reject the object/property dichotomy altogether (e.g., Alfred North Whitehead, who holds that the fundamental entities are neither objects nor properties, but events). Nonetheless, it should furnish the reader with a good understanding of what metaphysics is. As the historical details given in the description suggest, the debate about the relation between objects and properties died down in the 17th century and only came to prominence again in the latter half of the 20th century. As it was for this debate, so it was for traditional metaphysical debate in general. This is not to say that important work in metaphysics did not take place during this period of respite, but as epistemology took center stage in philosophy during the 18th and 19th centuries, a great deal of traditional metaphysics was sidelined, and in fact directly attacked by significant philosophical figures (e.g., by Hume and Immanuel Kant). This negative attitude was strengthened during the first half of the 20th century under the influence of two major philosophical movements: *logical positivism* in the 1930s and 1940s, and *ordinary language philosophy* in the 1940s and 1950s. Those from each movement were apt to complain that traditional metaphysical claims are either meaningless or confused. As these movements died away—and owing to the work of a number of pioneering philosophers in the 1940s and 1950s who were unafraid to tackle metaphysical issues head-on despite the prevailing negative attitude—metaphysics slowly regained its status as one of the central areas of philosophy. Quine, mentioned earlier, deserves special emphasis as being particularly influential in this regard. In the 1940s, he expounded a criterion of ontological commitment utilizing the methods of formal logic. According to this criterion, one gains a commitment to particular objects by accepting a given discourse (e.g., to numbers by accepting mathematical discourse). Although Quine's criterion has not been universally accepted, discussion and development of Quine's work fueled the revival of metaphysics. By the mid-1980s the revival was complete and is still going strong today.

The Influence of Metaphysics

As a foundational area of inquiry, the influence of metaphysics in other areas of philosophy is profound. Indeed, the influence in certain other areas is so extensive that those areas are best thought of as being subareas of metaphysics itself. For example, metaphysics predominates in the philosophy of mind, where the major questions regard the metaphysical nature of the mind/mental properties and their relation to physical objects/properties. Similarly, in the realm of personal identity the major questions regard the metaphysical nature of persons over time. But even in areas of philosophy where metaphysical concerns are not primary, metaphysics plays a central organizing role. This is true in ethics, epistemology, aesthetics, the philosophy of science, and practically all other areas. Again, a full survey of its influence is not possible in this short entry; instead an illustrative example is provided.

In ethics, one fundamental question concerns the metaphysical nature of moral properties, and seminal contributions in this area have focused on just this issue. Historically, for example, Plato conceived of goodness as a Form (i.e., the Form of the Good), knowledge of which is necessary for any other knowledge to be of benefit to us. In more recent times, G. E. Moore has advanced the position (in *Principia Ethica*) that moral properties are *sui generis* (of their own special metaphysical kind) non-natural properties that we come to know via a special faculty of moral intuition. This position, though now widely rejected (due in large part to John Mackie's argument that such properties are "metaphysically queer"), has served as a touchstone in contemporary debate, with many developing the position that moral facts are natural facts, a view known as *metaphysical naturalism*. Such positions have been developed by Michael Smith and Phillipa Foot, among others.

The influence of metaphysics in the sciences is a more contentious matter. Some preeminent scientists have gone so far as to claim that philosophy as a whole has no bearing whatsoever on science. Stephen Hawking, for example, famously declared that philosophy is *dead* on the grounds that philosophers have not kept up with developments in science. However, Hawking's claim provoked a robust response from other scientists and philosophers, with many suggesting that Hawking

himself had failed to keep up with developments in philosophy, and in particular metaphysics. Critics of Hawking's view in both science and philosophy have pointed out that the interpretation of scientific theories is itself a metaphysical enterprise, and that philosophers and scientists work fruitfully alongside each other in an effort to clarify and understand our best scientific theories. Consider the questions: (1) Is space-time in general relativity best thought of as an independent substance? (2) Does the mind play a fundamental role in the collapse of the wave-function in quantum mechanics, as currently understood? (3) Can neuroscience give us anything more than correlations between brain states and states of consciousness? Each of these illustrative questions, properly understood, have both scientific and metaphysical elements. Whereas scientists are experts in the empirical and mathematical methods necessary to obtain a clear view of how to answer them, metaphysicians are experts in the conceptual methods that are no less necessary. To understand the questions, we need to know the empirical facts, which is what science provides; but we also need to know how best to conceptualize the structure of those facts, which is what metaphysics provides. As such, if we want to progress beyond a purely instrumental understanding of science, metaphysics and science must be considered as integrated disciplines with the same fundamental goal: that of understanding the fundamental nature of reality.

METATHEORY

A metatheory is a set of beliefs, principles, and assumptions that people hold about what is real (ontology) and how individuals come to know reality (epistemology). Different metatheories involve different sets of beliefs and assumptions, but some form of metatheory underlies and conditions all theoretical and empirical work undertaken in the sciences, engineering, and mathematics. As sets of background concepts and presuppositions, metatheories demarcate what is sensible, meaningful, and appropriate in the theories and methods constructed to explain the world. Whereas theories take empirical phenomena (i.e., things and activities in the natural world) as their objects of study, metatheory takes theories themselves (and concepts more broadly) as the objects of study. As a practice, therefore, metatheorizing involves philosophical inquiry into—in other words, conceptual analysis of—theory and method. Metatheorizing encompasses a diverse cross-section of activities. These include philosophical analysis and synthesis of the background concepts and assumptions of metatheories themselves, as well as examination of what metatheoretical frameworks underlie and inform different theories and methods of a discipline. They also include application of specific metatheoretical principles, such as beliefs and assumptions about what constitutes good science or theorizing, to the analysis of theory and method itself.

Mapping the Conceptual Space of Metatheory

Basic *common sense* or *folk* beliefs and assumptions about the nature of reality—about how the world is organized, for example, or what being alive and being human entail—inform everyday human experience, constraining how people perceive and conceive of the world and themselves. These various beliefs and assumptions develop as a function of people's lived engagement with their physical and cultural environments. However, they remain largely backgrounded in the sense of being implicit and not something of which most people are consciously aware. A critical form of metatheorizing occurs when philosophers render explicit these commonsense beliefs and assumptions and

then proceed to organize and systematize them into coherent, principled sets, namely metatheories.

Stephen C. Pepper's book *World Hypotheses: A Study in Evidence* provides a paradigmatic example of this kind of metatheoretical activity. In his classic and heavily influential 1942 publication, Pepper argued for a total of six different metatheoretical frameworks of belief and assumption, only four of which he considered to be adequate models of reality: *formism*, *mechanism*, *contextualism*, and *organicism*. Each framework, or worldview, offers a distinct characterization of the nature of reality and truth, represented by a defining root metaphor. For example, likening the universe and everything in it to a machine constitutes the root metaphor of a mechanistic world view, whereas likening the universe and everything in it to an organic whole constitutes the root metaphor of an organicist world view.

Continued conceptual analysis of Pepper's world view designations has established possibilities for further syntheses. Willis F. Overton, for example, has argued that properties of a contextualist world view, such as its characterization of the universe as inherently active and ever-changing, can be subsumed under the integrative, holistic focus of organicism to yield a synthesis of both worldviews. This overarching worldview framework, which Overton has termed the *process-relational paradigm*, emphasizes multiple, irreducible levels of organization in reality and highlights the importance of adopting multiple epistemological perspectives on any given phenomenon. Its metatheoretical rival, termed the *Cartesian-split-mechanistic paradigm*, is akin to Pepper's mechanistic worldview and emphasizes the reduction of all complexity in the universe to one true reality: a foundational set of fixed elements or substances (e.g., atoms) of the universe. These elements exist independently of one another, and, through linear associations with one another, serve as the driving force behind the bottom-up generation of all structural complexity.

Overton's contrast between process-relational and Cartesian-split-mechanistic paradigms shares many similarities with another prominent worldview divide, namely between process and substance ontologies. Whereas a *process ontology* considers processes, rather than substances or things-in-themselves, as primary to all existence, *substance ontologies* characterize the universe's foundational

state in terms of fixed, elemental substances. Some form of substance ontology has conditioned much of scientific thought since the 17th century. Since the end of the 20th century, however, increasing calls of support for the adoption of its metatheoretical rival, process ontology, have emerged across a variety of scientific disciplines, as illustrated, for example, in Daniel J. Nicholson and John Dupré's 2018 edited volume *Everything Flows: Towards a Processual Philosophy of Biology*.

Uncovering the Metatheory Behind Theory and Method

Metatheorizing about metatheory is an exercise largely confined to the realm of philosophical discourse. Another form of metatheorizing, however, extends conceptual analysis to actual theory and method in scientific and other disciplines. In this form of conceptual analysis, various theories and methods are subject to critical examination in order to establish the metatheoretical beliefs and assumptions upon which they are founded. Recall that such underlying beliefs and assumptions profoundly affect how scientists think about their respective disciplines, from defining what constitutes a problem to be investigated and what questions to ask, to how to engage in empirical work or interpret empirical findings. As a result, explicitly identifying the metatheory that informs and constrains empirical and theoretical work offers a critical guide for understanding the conduct of all theoretical and methodological activity.

For an example of how this form of metatheorizing can unfold, consider the classic nature versus nurture debate in the psychological and life sciences. As typically conceived, the debate concerns whether nature (in the form of endogenous factors such as genes) or nurture (in the form of exogenous factors such as the physical and cultural environment) is primarily responsible for the development of an organism's traits. Both theoretical camps involved in this debate would seem to have little in common. However, conceptual analysis reveals some striking similarities in their background assumptions. Both nature and nurture theories model organisms as passive, as mechanistically acted upon and driven either by forces outside them or by forces within them. Both also presuppose that *nature* and *nurture* constitute independent sources

of trait development—sources that may combine additively. Both theories, in other words, derive from a common worldview: mechanism. This has enabled *resolution* of the debate in the form of integrated theories that treat both nature and nurture as interacting sources of development.

Debate still persists, however, over precisely what is entailed by forces of nature *interacting* with forces of nurture. At this level of the debate, conceptual analysis reveals a deeper, metatheoretical divide over how to conceptualize the interactions that occur between nature and nurture. On one side of this metatheoretical divide are those who see interactions as decomposable into distinct nature and nurture components, each of which plays a distinct role in the formative process. For example, factors of nature predispose toward a certain trait, but factors of nurture are needed to trigger, or actualize, that predisposition. From this metatheoretical vantage point, factors of nature and factors of nurture are ontologically independent and can therefore be legitimately separated through methodological analysis to determine relative levels of influence. On the other side of this metatheoretical divide are those who see the dynamic process of interaction itself as the driver and source of all traits. For example, an organism's traits constitute genuinely emergent products of interaction, irreducible to the *components* of the interaction themselves. From this metatheoretical vantage point, it makes no sense to think about nature and nurture as separable or different sources of traits. Likewise, methodologies that seek to study the distinct influences of nature relative to nurture are considered inherently faulty.

This extended example illustrates how important it is to reveal what metatheoretical frameworks underlie theory and method. When conceptual analysis indicates that two competing theories share common metatheoretical assumptions, then such theoretical debate can be readily resolved through empirical means. However, if a theoretical debate reflects a metatheoretical divide, then that debate exists beyond the realm of empirical investigation and therefore cannot be adjudicated through empirical activity. Such debates are philosophical in nature because different metatheories operate according to different truth criteria concerning the nature of reality and what methods are appropriate for knowing that reality.

What Makes Good Science: Evaluating Theory Using Metatheory

Metatheoretical activity is crucial for the development of a healthy scientific discipline, yet such activity also takes place outside the realm of science. In mathematics and logic, for example, metatheories often function as contexts in which theories and operations can be examined, as if from the outside. A metatheoretical level includes all operations of the level *beneath* it and therefore gives mathematicians and logicians an objective perspective from which to analyze the characteristics and functions of those operations and to formalize metatheoretical operations that subsume them. Likewise, in linguistics, a metalanguage is a language that is built to analyze the elements of an *object* language without being limited by, or even contained within, that language.

In scientific disciplines, metatheoretical beliefs and assumptions about the very nature of *proper* scientific values and orientations necessarily inform the evaluation of any given theory. Therefore, yet another critical activity of metatheorizing involves applying these ideas about good science to the analysis of theory and method itself. When scientists evaluate the cogency and coherence of theories and of the hypotheses and conclusions drawn from them, they are drawing upon a set of metatheoretical principles for judging the scientific appropriateness of theory construction and methodological implementation. When scientists ask if a theory is logical, internally consistent, parsimonious, falsifiable, ecologically valid, or consistent with other accepted theories within a scientific domain, they are appealing to a set of metatheoretical presuppositions for what makes good theory. Whether any of these questions make sense in adjudicating theory is an issue that itself derives from metatheoretical presuppositions. For example, some scientific debate exists over the utility and importance of parsimony in theory construction. Such debate reflects metatheoretical division between worldviews (such as the Cartesian-split-mechanistic paradigm) that see all complexity as reducible to basic elements and substances and worldviews (such as the process-relational paradigm) that embrace the importance of contextualizing phenomena within different levels of organization and analysis.

Revealing, examining, or constructing the criteria that scientists and philosophers alike use to formulate and answer questions about the viability of scientific theory and practice constitutes an important form of metatheorizing. Part of these criteria apply not just to single theory building but also to the integration of different theories. Are the elements from multiple theories consistent with each other? What integrated theoretical framework emerges by combining theories? What unique questions might this new framework compel or answer?

Importantly, the practice of building more inclusive theoretical frameworks from existing theories is itself conceptualized differently within the realm of metatheorizing. For some scientists and philosophers, metatheory operates on a qualitatively different level than theory does. Although efforts to integrate different theories, like efforts to evaluate individual theories, draw on a form of metatheorizing, the resulting integrated theories are not themselves metatheories. These higher order syntheses of theories still belong to the domain of theory, tied directly to empirical observation. Scientists have simply used the tools of metatheory to form integrated theories or have reflected on how metatheoretical assumptions and orientations have influenced the process of integration.

For other scientists and philosophers, however, most notably Steven E. Wallis, the overarching theory that results from combining two or more theories itself forms a metatheory. Wallis has argued that one of the key aspects of metatheorizing involves analysis of the common elements of various theories and an integration of those elements into a larger framework. This framework constitutes a metatheory in relation to the theories or elements that it integrates, and the work of metatheory is often centered on the formation of these increasingly comprehensive, discipline-uniting frameworks. Thus, even within metatheoretical circles themselves, debate ensues over where to draw the dividing line between theory and metatheory proper.

MODELING

Models are of great importance in the natural and social sciences for investigating phenomena and making causal inferences. A wide range of subjects has been studied using models, including biology, communications, economics, education, geology, political science, psychology, and sociology, among others. Such models differ in many ways, but they all aim to represent reality indirectly: The goal is to scrutinize reality through an artificial system that resembles, in some important aspects, the properties of the world that people are attempting to understand. By focusing on some aspects of the target phenomena, models are able to provide manageable representations that can eventually lead to further understanding of those phenomena.

Representing human behavior by modeling is by no means easy, however, and can be a challenge to various disciplines. Researchers are faced

with a number of modeling problems. For instance, much social science research is based on nonexperimental data, such as obtained by survey or quasi-experiment. Moreover, unlike studies in natural sciences, variables to be modeled are unavoidably measured with error, and failing to take measurement error into consideration yields unreliable statistical inferences. In addition, measurements in social sciences may involve categorical and nominal variables, such as gender and ethnicity, besides the quantitative and continuous variables. Finally, with longitudinal data gaining popularity, new modeling methods are needed to take repeated measures into account. This entry provides an overview of how modeling is applied in different disciplines and daily lives and introduces as examples four commonly used models in social sciences, namely categorical models, linear models, nonlinear models, and structural equation models.

When to Use Models

Models are everywhere in our daily lives, and understanding models can help people to become intelligent citizens, think in a clearer way, better understand data, and better strategize and plan. As the British statistician George E. P. Box famously noted, all models are wrong, but some are useful. It makes sense that models can be wrong, given that they are simplifications and abstractions of reality, but how can models be useful for people to work in a better way?

Modeling is nowadays the language not only of the academy but also of a variety of other domains. People from every discipline are using models to enable them to achieve their goals. Financial analysts on *Wall Street* are using models to forecast a corporation's profitability or determine the benefits of a merger. Biologists are using models of the brain to investigate where there are pathways between the neurons. Sociologists use models to identify effects of people's actions and behaviors, and psychologists model to measure people's attitudes. In political science, people use the spatial voting model to predict voting choices based on candidates' and voters' respective political orientations. Linguists also use models to understand the structure of a language under

study. And in daily life, it is not uncommon to receive advice from one acquaintance and the exact opposite advice from another. One possible way to adjudicate between such opposing counsel is by constructing models that can stipulate the conditions under which it would be appropriate to follow each recommended course of action, respectively. Although the actual application of modeling differs from discipline to discipline, in a general sense, modeling is useful for people to think about and to make sense of the world, and perhaps understand how the world could work in a better way.

How to Conduct Modeling

Modeling is a multistep process that can enable people to think more logically. To construct a model, the first step is to decide what factors matter most in determining the outcome one is interested in. Suppose we want to write a model of where students choose to go to college, and there are over 4,000 universities and community colleges in the United States. These institutions vary in terms of the academic resources, reputation, location, costs, and other factors, which is one aspect of the model. The other aspect is that of the students who apply for acceptance at these colleges and universities. The factors that may be relevant in influencing their application decision could be their standardized test score (e.g., SAT), grade point average (GPA), the subject they want to study, and the cost of tuition and other fees. These are determinants that jointly influence students' final decision of which school to attend. For instance, a high school graduate with a 2.5 GPA may be unlikely to apply to Harvard University, implying that GPA may be a variable predicting the outcome. However, in most of the cases, the outcome is not solely determined by a single factor. It is possible that a student with a 4.0 GPA will choose a less prestigious school than Harvard because the former institute provides them with full funding or may chose Stanford over Harvard because of the location. In short, there are multiple relevant factors that should be considered in modeling to understand a phenomenon. Once these factors are identified, we need to think about and establish the

relationships between those factors and make sense of the data.

Why Conduct Modeling?

Social and natural scientists use models to help them understand data better. First, modeling enables people to understand the patterns of data. For instance, the relationship between two variables could be a straight line or a cyclic curve, which enables researchers to get better sense of a large amount of data and make inferences. Therefore, in addition to knowing the patterns, people make use of models to make predictions. We can use data to construct a model and predict a point value from that model. Suppose we want to know how crime rate is related to residents' poverty level and predict the crime rate of a specific community. If the pattern shown in Figure 1 was obtained from the data collected, we know that there is a positive linear relationship between the crime rate and residents' poverty level. Given the

poverty index of a specific community, we are able to make a prediction of the crime rate at that area.

Prediction is not precise, however, and is susceptible to errors. In that case, people are usually interested in not only the point estimate but also the bounds of that estimate to tolerate estimation errors, which is the third way modeling is used. Suppose a chief financial officer of a company wants to know from an economic advisor what the inflation rate will be 10 years from now to make a long-term financial plan. The advisor can hardly answer such question without a sophisticated economic model. Moreover, the model will not only give a point estimate but also provide a range. It is not feasible for a model to produce an exact estimate in the social sciences, such as inflation rate, because too many contingencies are involved. Such complexity and uncertainty make the bounds more valuable, in that people are able to make a comprehensive decision based on the upper and lower bound. Finally, although in many cases people prefer making predictions with models, there are those who use models to estimate

Figure 1 Pattern Between Crime Rate and Residents' Poverty Level

data from the past and to figure out what the past was like. The reason could be that people (e.g., anthropologists, archaeologists, and geologists) sometimes have insufficient access to the data from the past.

In short, modeling enables people to make better sense of data and make predictions for the future and estimates from the past. By doing so, people have better chances to make wiser decisions, strategize better, and design things better. For illustration, let us examine four commonly used models.

Categorical Models

Categorical models, regarded as the simplest of models, are used to classify subjects into different categories on the grounds that such classification can be useful to make better sense of the data. Such usefulness can be reflected by explaining some of the variance in the data set. Here is an example. Suppose that six students took the math exam and got the following scores: Amy scored 100; Ben scored 75; Emily scored 80; Helen scored 90; John scored 65; and Tom scored 70. If we are interested in the variation of these six students' math scores, we need to first calculate the average grade of this group of students, which is $(100 + 75 + 80 + 90 + 65 + 70)/6 = 80$. In calculating the variation, the *sum of squares* (SS) is always applied in statistics to (a) convert negative values into positive ones and (b) to amplify deviations. So the variation is $(100 - 80)^2 + (75 - 80)^2 + (80 - 80)^2 + (90 - 80)^2 + (65 - 80)^2 + (70 - 80)^2 = 850$.

As variation is the part that is left unexplained, a possible way to reduce the variation is to explain why certain subjects have higher values while the other values are lower by categorization. For instance, one way to categorize in this case is by gender. In such case, the average grade and variation for the male group is $(75 + 65 + 70)/3 = 70$ and $(75 - 70)^2 + (65 - 70)^2 + (70 - 70)^2 = 50$, respectively, and for the female group is $(100 + 80 + 90)/3 = 90$ and $(100 - 90)^2 + (80 - 90)^2 + (90 - 90)^2 = 200$. Such categorization by gender substantially reduces the amount of variation left over from 850 to $90 + 200 = 290$. We initially have 850 units of variation that cannot be explained. However, with the categorical model indicating that female students on average

got higher grades than male students in this exam, $(850 - 290)/850 = 65.9\%$ of the total variation was explained. The percentage of variation that is explained by the model is referred to as *R square* (R^2), which falls between 0 and 1. A close-to-zero R^2 indicates that the model fails to explain much variation in the data set, while a larger R^2 shows the models' effectiveness in statistically explaining the data. By knowing that gender explains much variation in students' math grades, further investigation could be conducted to identify the reasons for male students' underperformance and design interventions targeting this group.

In real cases, there are many more subjects than the number in this example, and more categories are needed. For instance, besides gender, a second dimension of categorization can be applied, such as their maternal education, and further categorize them into more groups. Despite different ways of categorization, the primary purpose of categorical models is to explain the variation of data. How to categorize things affects how people think about things, and what decisions they are going to make.

Linear Models

In linear models, there are some explanatory or independent variables typically denoted as X , and outcome or dependent variables referred to as Y . A major activity in linear models is to identify the dependence of Y on X . As noted by Trevor Hastie and Robert Tibshirani, there are three goals of linear modeling: (a) description, to find out the process by which the outcome variables is generated, (b) inference, to detect the contribution of each explanatory variable in predicting the outcome variables, and (c) prediction, to forecast the value of an outcome variable for a specific combination of the values of the independent variables. For instance, public health researchers interested in lung cancer may specify a linear model to describe the process by which lung cancer incidences occur, to infer whether using tobacco increases the risk of lung cancer, and to predict the likelihood to get cancer of a person who uses a high volume of tobacco (X_1), and one who consumes few vegetables (X_2) to get cancer.

A simple linear model can be represented as $Y = \alpha + \beta X$, where Y , the predicted value, is a function of X . α is the *intercept* and β is the *coefficient*. Figure 2 illustrates a typical graph of linear regression that the dependent variable is on the Y -axis while the independent variable is on the X -axis. So the outcome variable can be predicted by $\alpha + \beta X$, and the value of Y equals α when β is zero. β , the slope of this linear model, indicates how fast Y will change if X changes by one unit. Two indicators of β are *sign* and *magnitude*. The sign of the coefficient indicates whether X influences Y in a positive or negative way, and the magnitude represents how much the influence is.

In social sciences, there are seldom outcomes that are predicted by a single variable, but usually, rather, by multiple explanatory variables. In those cases, we need a multiple linear regression model, represented as

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2$$

Since the regression line or the predicted value can hardly be exactly the same with the value in population but leave part of variance unexplained, which is referred to as *error* (ϵ_i), the model can be represented as follows:

$$Y_i = \alpha + \beta_1 X_{i1} + \beta_2 X_{i2} + \epsilon_i$$

In this model, the coefficients α and β_1 and β_2 are the population regression parameters; the central object of regression analysis is to estimate these coefficients. This model is similar with the Y model in terms of the form as the variables (X_1 , X_2 , Y) and the coefficients we are interested to study are similar; however, the two models are different because in the Y model we focused on what the best line/plane/hyperplane is for a *given data set from a particular sample*. It is rarely true that researchers are only interested in this sample observed. Instead, they want to make inferences of the whole *population*. If we want to predict students' SAT Verbal scores (Y) with their SAT Math scores (X_1) and Teachers' Pay (X_2) in population, the model can be explained like this: The intercept α is the predicted value of Y (SAT Verbal) when both X_1 (SAT Math) and X_2 (Teachers' Pay) are 0. β_1 represents the effect on Y (SAT Verbal) of a one-unit increase in X_1 (SAT Math) holding X_2 (Teachers' Pay) constant. β_2 is the effect on Y (SAT Verbal) of a one-unit increase in X_2 (Teachers' Pay) holding X_1 (SAT Math) constant. As the predicted value Y can hardly be the same as Y_i in reality, ϵ_i represents the aggregated omitted causes of Y in the population, or put differently, the causes of Y beyond the explanatory variable X .

Figure 2 Linear Regression Model

Nonlinear Models

In the real world, many relationships are not linear, and there are many more nonlinear functions than linear ones. For example, the relationship between X and Y can be fitted in a quadratic function, as shown in Figure 3. There are in general two ways to deal with nonlinear models. First, nonlinear models can be approximated with linear functions. Both nonlinear functions in Figure 3 can be approximated by two linear functions according to the slope: The first linear function is from the beginning of the semester to the final exam, and the second function is from the final to the end of the semester. Similarly, regarding cubic, quadratic, and more complicated models, they can also be approximated with a sequence of linear functions. However, analyzing nonlinear models in this way can produce much error and leave considerable variance unexplained. The second way is considered better than the first from this aspect, by including nonlinear terms in the model as follows:

$$Y = \alpha + \beta_1 X + \beta_2 X^2$$

In this model, Y is the function of X and X^2 . As the graph of a quadratic function is a parabola, if $\beta_2 < 0$ (or is a negative number), the parabola

opens downward, and if $a > 0$ (or is a positive number), the parabola opens upward. Instead of having X^2 in the model, the nonlinearity can also be presented in many other ways, such as $\sqrt{X}$, $\ln(X)$, $\sin(X)$, and $\cos(X)$. However, which nonlinear model to choose should be based on both theory (or previous research) and the percentage of variance explained.

For the multivariate nonlinear model, the function can be represented as

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_1^2 + \beta_5 X_1 X_2$$

α is the intercept representing the average value of Y when $X_1 = X_2 = 0$;

β_1 is the effect of a one-unit increase in X_1 on Y when $X_1 = X_2 = 0$;

β_2 is the effect of a one-unit increase in X_2 on Y when $X_1 = X_2 = 0$;

β_3 is the effect of a one-unit increase in X_1 on the slope relating X_1 and Y ;

β_4 is the effect of a one-unit increase in X_2 on the slope relating X_2 and Y ;

β_5 can be interpreted as either of the following: (a) for a fixed value of X_1 , β_5 is the effect of a one-unit increase in X_2 on the slope of the relationship between X_1 and Y or (b) for a fixed value of X_2 , β_5 is the effect of a one-unit increase in X_1 on slope of the relationship between X_2 and Y .

Structural Equation Models

Structural equation modeling (SEM), also referred to as *simultaneous equation models*, is a comprehensive statistical approach to testing hypotheses about relations among *observed variables*, which are measured, and *latent/unobserved variables*, which are not measured. In an SEM diagram, measured variables are often represented by rectangles or squares, while latent variables are indicated by ellipses or circles. The error terms for measured variables are represented as "E" and the error is referred to as *disturbance* for latent variables, represented as "D." The error terms represent residual variances within variables not accounted for by pathways hypothesized in the model. Structural equation models consist of two parts, a *measurement model* and a *structural model* (Figure 4). The measurement model deals

Figure 3 Nonlinear Models

Figure 4 Structural Equation Modeling

with the relationships between measured variables and latent variables, while the structural model only deals with the relationships between latent variables.

SEM is a methodology used to represent, estimate, and test the hypotheses of relationships between variables. Differently from the linear regression models, the variables in SEM are addressed as the *exogenous variables*, which are not caused by any other variables in the model, and the *endogenous variables*, which are explained by exogenous variables. SEM is also used to test hypothesized patterns of directional and nondirectional relationships among a set of observed variables and latent variables. There are generally two goals in SEM: (a) to understand the patterns of correlation/covariance among a set of variables and (b) to explain as much of their variance as possible with the model specified.

There are both similarities and differences between traditional statistical methods, such as the

linear regression models, and the SEM. SEM is similar in several ways to traditional methods like correlation, regression, and analysis of variance. First, both traditional methods and SEM are based on linear statistical models. For instance, the confidants of the *path analysis*, a subset of SEM used to examine causal relationships between two or more variables, can be obtained by running a sequence of multiple regressions. Second, statistical tests associated with both methods are valid only if certain assumptions are met, such as normality; traditional methods assume a normal distribution and SEM assumes multivariate normality. Third, neither linear regression models nor SEM offers to test causality. In other words, no causal relationships can be tested with SEM.

Despite the similarities, SEM has several noteworthy advantages over traditional models. First, unlike traditional methods which specify a default model (e.g., $Y_i = \alpha + \beta_1 X_{i1} + \beta_2 X_{i2} + \epsilon_i$), SEM offers no default model and places few

limitations on what types of relations can be specified. However, the model needs to be estimated and tested by formal specification, which requires researchers to support hypotheses with theory or research and make conceptual sense of the specified model. Second, SEM is a multivariate technique incorporating both observed (measured) and unobserved (latent constructs) variables, while traditional techniques analyze only measured variables. Such technique enables multiple related equations to be solved simultaneously and allows researchers to take into consideration the imperfect nature of measuring observed variables. That the latent variables are assumed to be free of random error is considered as a significant advantage of SEM because error has been estimated and removed, leaving only a common variance. SEM explicitly specifies error, while traditional methods assume measurement occurs without error. Finally, unlike traditional analysis which depends on significance tests alone to determine group differences or relationships between variables, SEM provides no straightforward tests but a number of model fit indices to evaluate the model fit, such as the chi-square test (χ^2), comparative fit index (CFI), Tucker Lewis index, Bentler–Bonett nonnormed fit index, root mean squared error of approximation (RMSEA), and standardized root mean square residual.

There are several rules of thumb to evaluate the adequacy of structural equation models. For instance, the χ^2 test is the test of absolute fit, which indicates the amount of difference between expected and observed covariance matrices. A χ^2 value close to zero with the probability level greater than .05 indicates little difference between the expected and observed covariance matrices. The CFI is the discrepancy function adjusted for sample size. CFI ranges from 0 to 1 with a larger value indicating better model fit. A CFI value of .90 or greater indicates acceptable model fit. RMSEA is related to residual in the model. RMSEA values range from 0 to 1 with a smaller RMSEA value indicating better model fit. Acceptable model fit should be indicated by an RMSEA value of .06 or less, as noted by Li-Tze Hu and Peter Bentler. For more details, see Rex B. Kline (1998).

According to Richard Arminger, Clifford Clogg, and Michael E. Sobel, several circumstances need

to be taken into account on the grounds that modeling in the social sciences is substantially different from that in the natural sciences in several aspects. First, because experimentation is usually not feasible and therefore often replaced by survey, the explanatory variables are not manipulated and well controlled by the researchers, which makes the explanatory variables random rather than fixed. Second, given the complexity of the phenomena in social sciences, there are often quite a large number of possible explanatory variables, compared with the small number of carefully chosen and controlled variables found in the natural sciences. Third, the measurement level of dependent variables is not always continuous but may also be dichotomous (e.g., yes-or-no questions), ordered categorical (e.g., Likert-type scale measuring attitude), or unordered categorical (e.g., choice of preference).

Concluding Remarks

Besides the categorical models, linear and nonlinear models, and structural equation models that have been the focus of this entry, there are many more models used in specific contexts such as multilevel modeling or hierarchical linear modeling, which deals with the nested structure in the data; Bayesian modeling, where a priori knowledge is applied before observing the data; latent growth modeling, which deals with longitudinal data analysis; and others. Although space limitations do not permit discussion of all models in a single entry, readers are encouraged to use the information provided here and the works listed below to explore modeling further.

NANOTECHNOLOGY

Nanotechnology is among the most important domains of leading-edge science and technology and is a highly promising field for future research. It deals with both theoretical and experimental structures at the nanolevel (10^{-9} of a meter). The origins of nanotechnology and nanoscience lie in physics, particularly the physics of condensed matter, which is the broadest of the fields of applied physics. Nanotechnology thus falls within the category of the science and engineering of materials. Significantly, in the 1 to 100 nm range, quantum effects come to bear, such as the quantum Hall effect or the Casimir quantum effect, among others.

Indeed, matter behaves differently at the macroscopic level than at the microscopic scale. Thus, a series of discoveries have been made leading to femtochemistry or femtobiology, for instance. The most important levels of the microscopic world exist at nanoscale:

- Mili = 10^{-3} m
- Micro = 10^{-6} m
- Nano = 10^{-9} m
- Pico = 10^{-12} m
- Femto = 10^{-15} m
- Atto = 10^{-18} m
- Zepto = 10^{-21} m
- Yocto = 10^{-24} m
- ...
- The Planck scale = 10^{-33} m

The Planck scale, named for theoretical physicist Max Planck (1858–1947), is the absolute limit in terms of space, beyond which—according to the current state of knowledge—nothing can be assessed. Corresponding to the Planck scale is Planck time which is 10^{-42} s, as the absolute limit in terms of time. The nanoscale stands out as perhaps the most exciting field in which different sciences and disciplines converge, such as physics, chemistry, engineering, mathematics, health sciences, among others.

The counterintuitive behavior of matter at the nanoscale calls attention to the structures of the atom, hence called *nanoparticles*. At very small scale, matter behaves differently allowing us to *see* quantum effects. Those quantum effects are crucial for the understanding of matter in a variety of fields and for working on quantum processes and phenomena.

The term *nanotechnology* was originally coined in 1974 by N. Taniguchi as a process consisting of separating, consolidating, and deforming materials by one atom or one molecule.

Origins

Four steps can be identified regarding the origins of nanotechnology:

- The search for the structure of the microscopic world in the framework of nanotechnology can be said to have begun in 1932, when E. Ruska, a German physicist, and M. Knoll, a German engineer, built the first transmission electron

microscope (TEM). The TEM made it possible to see objects at the molecular level, particularly proteins and the fine structure of metals, for it was possible to see particles smaller than 200 nm by focusing a beam of electrons rather than light through an object.

- On December 29, 1959, Richard Feynman, a leading scientist in quantum physics in general, and in quantum electrodynamics in particular, gave a talk at the California Institute of Technology (Caltech) addressed to the American Physical Society with the title “There’s Plenty of Room at the Bottom,” discussing the theoretical possibility of arranging individual atoms.
- Further on, in the 1970s, Norio Taniguchi, working at the Tokyo University of Science, coined the term *nanotechnology* as the process of manufacturing materials from single atoms or molecules.
- In 1986, K. Eric. Drexler published *Engines of Creation*. The book presents the basis for the most favorable possibilities of research in molecular technology as well as the perils and hopes of the new field. It remains as a landmark in nanotechnology and a source for those in the forefront of the discipline.

Key Developments

Three conceptual, technological, and methodological levels are decisive for the development of nanotechnology: microscopy, synthesis, and assembling. They are closely intertwined. The key term used in nanotechnology at large, however, is *invention*. Indeed, the invention of novel methods, materials, techniques, and approaches comprise the very history of nanotechnology. Briefly discussed below are some of the significant achievements of the people who have played key roles in advancing the path of nanotechnology.

The development of microscopy and its technical refinement has been crucial for the history of nanotechnology. In 1936, the field emission microscope, originally invented by Erwin Müller in Germany, made possible the near-atomic resolution images of materials. In 1981, Gerd Binnig and Heinrich Rohrer invented the scanning tunneling microscope, which allowed for the first time the creation of spatial images of individual atoms. In 1986, Gerd Binnig, Calvin Quate, and Christoph

Gerber invented the atomic force microscope that allows to view, measure, and manipulate materials and forces at the nanoscale.

Based on microscopy, a series of discoveries were made in a range of fields including chemistry, nuclear and quantum physics, electronics, and optics, with surprising and fruitful applications in a variety of domains. Thus, in 1981, A. Ekimov discovered *nanocrystalline*, semiconducting quantum dots in a glass matrix, which opened the gates for further work on electronics and optics with important impact in the health sciences. In 1985, *fullerene* (named after polymath and systems theorist R. Buckminster Fuller), an allotrope of carbon forming a closed or partially closed mesh, in a variety of configurations such as spheres, tubes, and ellipsoids, was discovered by H. Kroto, S. O’Brien, R. Curl, and R. Smalley who worked at Rice University (USA).

To the advances of microscopy, as mentioned, the scanning tunneling microscope and atomic force microscopy continue to deepen, enlarge, and enhance nanoscience research.

During the 1990s, nanotechnology companies begun to be established. To date, the number of companies in the field number more than 100 worldwide. In 1991, S. Iijima discovered the carbon nanotube, a structure that exhibits great properties of strength and electrical and thermal conductivity, fundamental in biological use as well as communications, and photonics. In 1991, C. T. Kresge discovered nanostructured catalytic materials MCM-41 and MCM-48, useful in water treatments, drug delivery, and other applications. Shortly afterward, in 1993, M. Bawendi at MIT invented a method for the controlled synthesis of nanocrystals. Synthesis subsequently became a key method in nanotechnology. Research along this line now influences computing, biology, and high-efficiency photovoltaics.

Along with synthesis, assembling becomes a salient feature of work in nanotechnology. In 1999, W. Ho and H. Lee were able to assemble a molecule with scanning tunneling microscopy. Little by little, similar to what was happening in the realm of genetics, in nanotechnology the work went from just *reading* the atom to *writing* it. Synthesis and assembling become regular methods and approaches that cross disciplines as varied as biology, chemistry, engineering, physics, and environmental studies.

Meaningfully, around the years 2000, several consumer products using nanotechnology began

appearing in the market modifying thus imperceptibly habits and preferences. Tennis rackets, baseball bats, nanosilver antibacterial socks, cell phones, cameras, displays for TVs, therapeutic cosmetics wrinkle-resistant clothing, automobile bumpers, and many other products have been developed until to date that are smoothly but drastically changing everyday life. Nanotechnology is becoming a cultural asset in the life of society. Fifteen industrial sectors can be accounted as leaders in industry and innovation based on nanotechnology.

In 2003, Naomi Halas, Jennifer West, Rebekah Drezek, and Renata Pasqualin developed gold nanoshells for the discovery, diagnosis, and treatment of breast cancer that avoid invasive treatments. The nanoshells are *tuned* so that they can absorb infrared light and identify malign tumors. This is clearly a fundamental path to noninvasive medicine as well as to personalized medicine.

In 2005, Erik Winfree and Paul W. K. Rothemund made possible computations in the process of nanocrystal growth by developing theories of DNA-based computation and algorithmic self-assembly. This offered a way forward to nonconventional computation as well as to biological hypercomputation that aims to shed light on the understanding of life generally.

In 2007, Angela Belcher built a lithium-ion battery with a common type of virus nonharmful to humans. Nanotechnology could thus be identified as one key aspect for the interplay of what has been called the *chip-cell interface*, or the next technological singularity. Such interplay may have important consequences for future research and technology.

The pace of discoveries and achievements is relentless, indeed. Thus, in 2009 and 2010, Ned Seeman helped create several DNA-like nanoscale robotic assembly devices and DNA-assembly lines making programming self-assemble complex processes and structures.

An Expanding Field

Nanotechnology was developed as applied science and it was so conceived for a long time. Subsequently, it has come to shed fresh light on life as well as on the materials under investigation. As such, it has morphed into the larger discipline of *nanoscience*.

Similar to what happened with genetics, the first period of nanotech, from roughly 1959 until the late 1990s, consisted in *reading* subatomic components at the nanoscale. From the 1990s until the present day, the process has included *writing* nanostructures: designing, synthesizing, assembling, and programming various nanoproducts and processes. Furthermore, whereas it was initially a field of interest for physicists and materials engineers, it has since deepened and enlarged its scope, encompassing also biologists, electrical and electronic engineers and computer scientists, environmentalists, and ecologists performing fundamental research on health. Only recently have some social scientists begun to join and nurture the field, thereby further enhancing its cross-disciplinary nature.

When working top-down, the study of nanotechnology moves from mechanical to thermal to optical processes, where sputtering and chemical etching are generally implemented. In other words, nanotechnology engages in the process of modifying materials in order to convert a bulk material into nanoparticles. Correspondingly, the bottom-up procedure uses atomic or molecular condensation that allows a reduction of biological structures or behaviors so that they, in turn, can lead to further chemical or electrochemical reduction. This allows the production of solid material via the sol-gel method and further to vapor deposition and the production of high-quality and high-performance solid materials.

Among the efforts to design, assemble, and program various products are those focused on developing nanorobots, either individually or also as part of swarm robotics. In medicine, they may one day be transported through the bloodstream to specific organs for cleaning up infections, eliminating tumors, or helping the immune system to produce antibodies, for example.

Layers and Materials

Two basic types of nanotechnology materials can be identified: thin films, layers, and surfaces; and multi-layer materials including nanotubes.

Monolayers were the first materials developed and have been implemented chiefly in fields such as chemistry, engineering, and manufacture of a number of devices. Some such materials consist of

one atom or are one molecule deep. Thin films and surfaces are widely produced for coating in general, pharmaceuticals, and in the energy sector.

Regarding multilayer materials, layer graphene stands out for its properties that make possible increased energy capacity of rechargeable batteries as well as enhanced energy storage, flexibility, and lightweight. Current research now anticipates the development and improvement of 2D and 3D structures including silicene (an allotrope of silicon), boron, and molybdenum oxides.

In this second regard, the most conspicuous materials in nanoscience are *nanotubes*, which were the first materials to be developed. Made of carbon, these are cylinders of one or more layers of graphene. Usually, carbon nanotubes range from 0.8 to 2 nm and 5 to 20 nm with lengths from 100 nm to 0.5 meters. Carbon nanotubes are used in biomedical and medical research, energy storage, automotive parts, water filters, coatings, and electromagnetic fields, among other applications.

Quantum dots are man-made semiconducting nanoscale crystals that can transport electrons. When semiconductor particles are small enough, quantum effects emerge, which limit the energies at which the electrons or holes (=absence of electrons) can exist in the particles. Nanocrystals could become an important component for self-assembled nanodevices. So far, the use of quantum dots has been in artificial environments, but some research is being carried out that aims at working also in real-world environments.

Graphene, like fullerene, is an allotrope of carbon consisting of a single layer of atoms arranged in a 2D honeycomb lattice. Graphene was properly isolated and characterized in 2004. It is a zero-gap semiconductor. Among current developments are monolayer and bilayer sheets, graphene superlattices, nanoribbons, graphene quantum dots, graphene oxide, graphene fiber, aerogel, nanocoil, and many others.

Fullerene, as mentioned earlier, consists of carbon atoms connected by single or double bonds that includes a wide family of forms, structures, and shapes named for instance as C_{20} , C_{60} , C_{70} fullerene, and several others.

Nanomaterials are produced in an either of two ways, top-down and bottom-up, always as synthesis processes. In the first case, the production consists of various milling techniques to

crush microparticles. Traditionally, thermal stress is involved and is energy-intensive. In contrast, bottom-up production is based on physicochemical of molecular or atomic self-organization. This method allows for better control of sizes, shapes, and ranges. Hydrothermal, sol-gel, and precipitation processes are regular practices here. Flame reactors working at temperatures around 1,200 to 2,000 °C along with plasma and laser reactors are used in industrial processes for the production of nanomaterials.

Nanorobotics is the process by which several procedures have been developed, such as nanofabrication, which produces nanomotors, nanoactuators, nanosensors, and the modeling of physical materials and processes at nanoscale. Nanorobotics comprises assembling nanometer-sized parts, the manipulation of biological cells or molecules. Rightly understood, nanorobots are nanomotors that are currently used in medicine, environmental studies, and electronics, for instance, to clear bacteria and toxins from blood or waters. Those nanomachines are activated by UV-light, DNA-origin-based nanorobots, light-induced nanotransducers, magnetic nanolink nanoswimmers, and other mechanisms and techniques. Usually, it is harder to produce nanorobots and nanomaterials than acting upon them or making them behave in a variety of ways.

Applications

Among the fields where nanotechnology is being both developed and applied are nanobiotechnology, nanoelectronics, nanoplasmonics (research on optical phenomena at nanoscale), food and agriculture, energy, environmental preservation; various methods and techniques in biomedicine aimed at fighting HIV, cancer, Alzheimer, and food-borne illnesses; the cement industry, construction, displays, furniture, and cosmetics.

Controversy has arisen over human ability and the use of nanotechnology to gain an advantage in sports; the practice is commonly referred to as *technology doping*. Some sports equipment where nanotechnology is being incorporated include tennis and badminton, golf, cycling, skiing, bowling, and archery. The materials used therein encompass carbon nanotubes, silica nanoparticles, fullerenes, carbon nanofibers, nanoclay, and nano-titanium.

In cosmetics, nanotechnology is being incorporated as UV filters and in drug delivery agents. In the automotive industry, this technology is currently present in nanovarnish, carbon black in tires, solar cells, nanofilters, fuel additives, fragrance in the passenger cabin, antiglare coatings, ultrathin layers, and electrochromatic layers, for instance.

As some observers and critics have pointed out, nanotechnology has gradually become more pervasive in everyday life, even if many people do not yet recognize it. The continuing growth of these developments will surely continue making nanotechnology and nanoscience a most salient development in the history of humankind.

The Kavli Prize in Nanotechnology

The Kavli prize awards breakthroughs in science at the atomic scale. It is awarded every 2 years and it was established in 2008. It can be considered as

the equivalent of the Nobel Prize in nanotechnology and nanoscience (Table 1).

Significantly, various awardees of the Kavli prize either had already been awarded, or will be awarded, the Nobel Prize, which is a clear sign of both the work's prestige and scientific rigor.

Science, Economics, and Politics

Finally, as it is well known, there is a scientific and political race around nanotechnology very much as it happened in the past with the exploration of outer space. The two leaders in the race are the United States and China, and the subject around which the race is defined is the course of the fourth industrial revolution in general and the role of artificial intelligence and the Internet generation 5 and 6 (5G and 6G) networks. To be sure, nanotechnology stands at the very center of the current and possible outcomes of artificial intelligence and the fourth industrial revolution. It

Table 1 Winners of the Kavli Prize in Nanoscience, 2008–2020

<i>Name</i>	<i>Country</i>	<i>University or Laboratory</i>	<i>Year</i>
Louis E. Brus	USA	Columbia University	2008
Sumio Iijima	Japan	Meijo University	2008
Donald M. Eigler	USA	IBM Almaden Research Center	2008
Nadrian Seeman	USA	New York University	2010
Mildred S. Dresselhaus	USA	MIT	2012
Thomas W. Ebbesen	France	University of Strasbourg	2014
Stefan W. Hell	Germany	Max Planck Institute	2014
Sir John B. Pendry	UK	Imperial College	2014
Gerd Binnig	Switzerland	Former member of IBM Research Laboratory	2016
Cristoph Gerber	Switzerland	University of Basel	2016
Calvin Quate	USA	Stanford University	2016
Emmanuelle Charpentier	France	Max Planck Institute	2018
Jennifer A. Doudna	USA	University of California	2018
Virginijus Siksnys	Lithuania	Vilnius University	2018
Harald Rose	Germany	University of Ulm	2020
Maximilian Harder	Austria	European Molecular Laboratory in Heidelberg	2020
Knut Urban	Germany	Max Planck Institute	2020
Ondrej Krivanek	UK and Czech Republic	R&D director at Gatan Inc., USA	2020

should be mentioned that the technologies and capacities of and around nanotechnology are extremely expensive, which means that a gap will be rapidly produced between those countries with human, technical, and scientific capacities and those countries that cannot afford the costs of the competition.

Indeed, an atomic force microscope, for instance, can easily cost over half a million dollars. Of course, a good laboratory working on nanotechnology needs more than that.

Currently, there are over 1,200 research groups, laboratories, and departments in universities worldwide. In 2020, the number of private industry and private laboratories exceeded 240. There are over 340 national and international initiatives and networks. Specifically working on raw materials, there are more than 310 groups and laboratories. Currently, there are nearly 200 groups, both private and public, focused on biomedicine and the life sciences. More than 900 companies—baseball bats, cosmetics, and so on—exceeds 900.

Furthermore, regarding education and research on nanotechnology, as of 2020 there are 67 B.A. degree programs, 157 master's degree programs, and 44 doctoral degree programs, which clearly shows both the importance and the trend of education and research in leading-edge science on nanotechnology. The number of journals either particularly focused on nanotechnology or that accept publications in the field has risen to 225, further illustrating that nanotechnology is rapidly becoming a major player in mainstream science.

NATURAL RESOURCES

A complex picture of how humans interact with natural systems emerges from the study of, and theorizing about, natural resources. All humans depend on our environment to some degree in satisfying our daily needs for food, shelter, and clothing. To gain those basic necessities entails that some residue is generated from processes related to natural resources extraction, exploitation and consumption. Beyond those basic facts, the amounts and forms of natural resource use vary greatly between locations, socioeconomic tiers, ethnicities, regions, cultures, and countries. Natural resources also present a particular challenge to the theoretical and practical toolkit of several overlapping disciplines such as geography, politics, law, economics, ecology, and environmental studies. One reason for this challenge is difficulty in accounting for all the resources used. Broadly defined, natural resources consist of any natural material considered useful or desirable to someone somewhere; but this can and often does change with location, scarcity, or cultural values. Sand, for instance, is a nuisance in Nevada, where the supply seems endless, but is exported to glass factories in Kentucky as a raw ingredient for glass manufacture. Conversely, water in desert regions can make the difference between life and death but has almost no value as a commodity in regions such as the American Southeast, where water is abundant. While we all need to use resources for food, shelter, and clothing, we consume far more resources indirectly through complex pathways between source and user. Thus, natural resources and how to acquire, store, process, exploit, distribute, buy, sell, trade, steal, divert, preserve, and conserve them—as well as the need to grapple with the residue of resource use—have demanded much time, thought and energy, as discussed in the sections that follow.

Types of Resources

Natural resources usually are considered in different ways, based on the broad categories of renewable and nonrenewable resources. The *non-renewable resources* are essentially finite. They

require an extremely long time to regenerate, which far exceeds human life spans. Therefore, in terms of human use, they are finite in their supply. Nonrenewable resources include the fossil fuels such as oil, coal, and natural gas as well as most metals. Because it takes millions of years for nature to create gold, once the amount of gold in a seam has been mined out, it will not regenerate, and the mine is considered empty or depleted. This is not the case for *renewable resources*, which can be regenerated within the life span of humans or, in some cases, they never deplete at all. Examples include surface water, forests, and most food production. For instance when forests are cut down, if trees are replanted then the forest can regenerate in a matter of decades. Similarly, taking water from rivers decreases the immediate quantity of the resource, but snow melt and precipitation will regenerate the fresh water over the seasons of the year. Within the renewable resources category a special subset exists known as *perpetual resources*, which exist whether we use them or not, and do not diminish with human exploitation. Perpetual resources include wind, solar, and geothermal resources. For example, capturing wind using a wind turbine will not decrease the amount of wind that blows; similarly, no matter how many solar collectors capture solar energy, it will never decrease the intensity or amount of incoming solar radiation. Resources are classified as *mobile resources* if they tend to change location or do not conform to notions of political boundaries or ownership. Migrating fisheries or herds of wild animals would fall into this category. This can also describe the negative impacts or residue of resource use such as air pollution or water pollution. Clouds of smog do not stop at customs checkpoints and do not conform to notions of political boundaries or ownership. *Common pool resources* (also called common property resources) are owned by all in theory even if accessed or utilized by only a few—the atmosphere, sunshine, or the oceans. The last classification, *potential resources*, is that category of things not yet considered to be resources but that could potentially become resources in the future. This category, by its very definition, remains elusive of quantification since the potential uses of resources for future generations will depend greatly on choices made

by today's generation, as well as new technologies, applications, and innovations. An example with positive implications would be the new emerging technologies that allow for the capture of methane for use as energy from decomposing trash. Today's landfills will likely become the next generation's sites of reclamation and mining, for the materials we toss away. On the negative side, species of plants and animals that become extinct can clearly never have the potential to become a natural resource for future generations. It should be noted here that these categories, although useful, are not always mutually exclusive. Groundwater, for instance, could be considered a renewable resource as long as the rate of withdrawing water from an aquifer does not exceed nature's ability to recharge that aquifer. Precipitation drops water on the land, some of which soaks into the soil, percolating down until it replenishes aquifers, within a span of months to years as part of the hydrologic cycle. However, we also have massive stores of groundwater that were the residue of melting as the last ice age receded roughly 13,000 years ago. This is essentially a hydrologic gift from a previous era that will not be replenished in our lifetimes. Exploiting that groundwater, as we currently do in semiarid agricultural regions in the Midwest, would be considered exploiting a nonrenewable resource.

Resources and Dominance

Throughout history, acquisition and control of natural resources has been the cornerstone of much economic, political, social, and foreign policy. The need to acquire and control resources has driven technological innovation as far back as the advent of the water wheel and the fence. From the beginning of human history, resources and the need or desire to acquire or dominate them form the basic logic of warfare, political maneuvering, and statecraft. One prime motivation for war has always been to secure one's own resources (defense) or plunder the resources (offense) of others. In a more productive direction, a core *raison d'être* for governments is to provide security to their citizens, often against armed invaders who seek to acquire natural resources. Another central focus of government is that of developing and exploiting the natural resources within its territory, though in modern

times conserving resources has become more of a concern. Throughout history, countries and empires assessed their strength in three basic metrics: military might, economic prowess, and amount of natural resource wealth. Clearly, advantages exist for those who control resources and disadvantages exist for those who do not. This reality has driven worldwide trends in geopolitical dynamics such as early global trade routes like the Silk Road; the rise of colonialism; global commodity chains; and multinational corporations and globalization. The variations in geographic distribution of natural resources around the planet form the stage upon which these tensions are played out and helps explain why there exist fundamental inequities between the developed world and the developing world—patterns that are commonly referred to as the *global north* and *global south*.

Capitalism and Accumulation

The idea of commerce and trade for profit goes back thousands of years. But not until the convergent evolution of capitalism, paper currency, and changes in political theories of value and property did human see the massive transformation in the political economy and concomitant use of resources that now exist in modern capitalism. Feudalism as a system of land tenure, social organization, and economy dominated for more than a thousand years before its dismantling, which began in the 16th century. In feudal regimes, the currency of power rested in the ownership of land that was exclusively owned by the nobility. The advent of mercantilism and the rise of paper currency allowed for increased accumulation of wealth, without the need for large tracts of land or the physical possession of metals such as gold or silver. Then, fundamental shifts in political and economic theory radically transformed how resources were valued, exploited, and consumed. As agrarian capitalism gave way to mercantilism, and then industrial capitalism, theories from philosophers John Locke (1632–1704) and Adam Smith (1723–1790) underpinned the coevolution of political and economic systems.

Smith challenged fundamental beliefs of mercantilism such as the idea that the world's wealth remained constant; therefore, accumulation of one state's wealth could only happen at the expense of

another's loss of wealth. Another theoretical foundation is Locke's theory regarding labor, which states that goods produced by nature have little or no value until labor is added to them. Locke posited that adding labor generates value for goods, and property is created through the application of labor. Locke also argued that said property derived from the application of labor was a natural right. Unlike the economist Smith, Locke did believe there were limits to accumulation. According to Locke, labor creates property, but man's capacity to consume inherently limits man's capacity to produce; any excess would just spoil, so why produce more than can be consumed? With the introduction of durable goods, however, this limit of consumption faded—as did the idea of limits to accumulation. Upon these twin pillars established by Smith and Locke, the fundamental ideas of industrial capitalism and private property were established, and it is this system that has dominated economic thinking for the last 200 frenetic years of expansion. Add to this the ideas of Jeremy Bentham (1748–1832) and John Stuart Mill (1806–1873) and the result is a system predicated on the belief that the greatest good for the greatest number arises when each individual maximizes his utility given the economic options at his disposal. Maximizing utility centers on maximizing profits, and that instinct drives the laws of supply and demand. It is upon these deeply embedded ideas that industrial capitalism feeds the desire to continually accumulate more wealth. Of course, natural resources form the basic raw ingredient in this philosophy of political economy. Nowhere in the basic premises of industrial capitalism is there any discussion of limits on accumulation of wealth, or of the consumption of finite resources.

Many critiques of capitalism exist, but the criticisms related to natural resources come most powerfully from Marxist perspectives. Marxists see capital not as a relation between people and things but as a social relation, and they point out that this relation is predicated on sustained exploitation of human labor by the few who own the means of production. Since the core motivation in capitalism centers on making profit, those who own the means of production are rewarded (with higher profits) for exploitation of labor, the environment, or both. From the Marxist perspective, a

system that is built around the belief that there are no limits to accumulating wealth, and that all trade should be unfettered, is fundamentally flawed. It generates a never-ending spiral of growth whereby natural resources are exploited and products are produced, which require more markets that generate more consumers who buy more things—which in turn generates more residue and more inequality, since only a few control the means of production. There is no steady state or equilibrium in a system built on inequality, predicated on endless exploitation of natural resources. But in fact we live in a finite world with finite natural resources.

Scarcity, Opportunity Cost, and Externalities

Economists find natural resources particularly slippery as an element of economic systems, and their attempts to grapple with natural resources provide us with useful ideas related to *scarcity*, opportunity cost, and externalities. A cornerstone of economics rests on choices and value. When an item is scarce its value will rise; thus as supply dwindles, demand rises and changes in prices reflect this shifting equilibrium. But the inability to determine scarcity or to count the amount of many natural resources skews all attempts at prediction of future trends. *Relative scarcity* occurs either with uneven distribution of resources, or when one group controls and limits access, ownership, or distribution of a resource—usually at the expense of other users. *Absolute scarcity* means depleting a resource to the point of exhausting it completely. As an example, oil is geographically concentrated in just a few places, so it is relatively scarce, and most developed nations import oil as an energy source. In the 1970s, Organization of the Petroleum Exporting Countries imposed an oil embargo restricting access to their oil, creating relative scarcity and pushing oil prices up. But on a planetary scale, oil is also a nonrenewable resource and subject to absolute scarcity as we exploit more and more of it. Knowing when that point of scarcity is reached can be extremely difficult to pinpoint as new reserves might be found (or not), new alternative fuels come into use, and new technologies change the rules of the game.

Economists developed the concept of *opportunity cost* as a metric for quantifying the consequences of choices. Opportunity costs arise when choices must be made among limited options, and choosing one option means an individual loses the opportunity to choose the other. Thus, if an individual chooses to go to university, that entails the lost opportunity of 4 years as an employed worker. Economists compare the relative merits of these two pathways by estimating associated costs and benefits of each path, such as higher income from future employment after university compared with lower income but more earning years. Natural resources elude such calculations because some resources we cannot live without, like water, while others form luxuries. Similarly, in some cases one resource can be substituted for another, but not in all cases. Water is needed to live, and no substitute will suffice if there is no water. Natural gas may be substituted for coal as a source of electricity as market prices vary, but both are nonrenewable resources. When they are gone, what then? Also, economists struggle to quantify lost opportunity costs associated with *not* using a resource. There is no easy way to quantify the opportunity cost of not cutting a forest, or not depleting a shared fishery or not polluting air versus cutting forests, overfishing, or polluting air.

Externalities pose similar problems. These are unaccounted for or unintended impacts from other activities that change hands without agreed upon prices, and often without knowledge or consent. This can be positive or negative, but negative impacts dominate economic debates. Water pollution is an externality that results from many industrial and agricultural activities, but it is not accounted for in the cycle of production, distribution, and consumption of products. Economists can quantify the price of land, seeds, fuel for tractors, storage and distribution of grain, prices of produce, and so on, but the resulting pollution in the waterways from agricultural runoff is not taken into account or quantified. It has no price, but clearly there is a cost. Usually externalities are disproportionately felt, but not by the producer or consumer. When a car factory pollutes a nearby river, it is not the manufacturer of cars who feels the impact, but completely unrelated people downstream. The inability to establish cost or value or price makes natural resources and polluting residues a gap that

resource economists still struggle to address. This imbalance in impacts of natural resource use or externalities resulting from resource exploitation has spawned the new interdisciplinary concept of *environmental justice*.

Malthus, Overpopulation, and Neo-Malthusians

Prior to industrialization, human population tended toward steady but slow growth. With births mostly canceled out by deaths, global population took nearly 50,000 years to reach the mark of 1 billion people, achieved in the early 1800s. However, after industrialization began, population growth rates skyrocketed and continue to do so today—with global population doubling to 2 billion in a century (early 1900s) then again to 4 billion by 1974 and the expectation of doubling again to 8 billion by the end of the current decade. The economist and demographer Thomas Malthus (1766–1834) first highlighted the dangers of overpopulation by connecting population growth rates with far less rapid growth rates in food resources as he studied the overcrowded slums of London. He famously noted as early as 1798 that population was increasing geometrically (or as we would now say, exponentially), while food production can only increase arithmetically. Simply put, population increases too rapidly compared with the rate of man's ability to increase food supplies, so population will outstrip food resources, and war, poverty, and famine would be inevitable at the point where the availability of food could not keep up with the need for it. His early theory on resource limitations remains embedded in our lexicon today; those who apply Malthus's theories to the current state of the world are known as *neo-Malthusians* and they share fundamental agreement that the Earth's agricultural capacity can only sustain a limited population. Although the exact number of Earth's carrying capacity is not known, we clearly will reach or already have reached beyond the population numbers that can be sustained; thus, overpopulation leads to persistent poverty and social degradation.

Malthus lived before the discovery of fossil fuels, the internal combustion engine, and electricity. These innovations have propelled rapid technological innovation that phenomenally increased

our capacity to grow food. Because the global population has massively increased and the dire predictions of Malthus have not yet occurred on a global scale, the debate continues, unresolved. Some suggest that the fulfillment of Malthus's predictions may merely have been delayed but are still correct and inevitable, and calamity is sure to occur at some point. Others believe Malthus's predictions will be avoidable because technological improvements will always keep pace with increased need for food. Neo-Malthusians have always been controversial, leading to much debate and dispute. One major criticism of neo-Malthusians' arguments points out that food distribution, not the production of food, remains a leading factor in persistent poverty. Thus, poverty would exist in some circumstances no matter the total population. Another criticism suggests that people will adapt to their changing environments and find alternatives to the depleted resources, be they food resources or other resources. The debate continues and now has expanded beyond food to include the wider reality of many finite resources, but the question remains as to whether Malthus was correct.

Tragedy of the Commons

In 1968, Garrett Hardin, an ecologist, set off a storm of debate across several fields of study with an article in the journal *Science* entitled "The Tragedy of the Commons," in which he reconsidered the social question of population issues, but with a focus on economic theory and natural resources. His argument continues to be a theoretical touchstone for much of the environmental and natural resource community, while its implications echo outward to many disciplines. According to Hardin, when individuals have unlimited access to natural resources, they will inevitably act in their best interests to maximize their own utility, that is to say, maximize their ability to *utilize* natural resources to satisfy needs or wants. If each individual profits by exploiting as much of the resource as possible, but the group as a whole shares in the negative utility caused by depletion of the resource, then each individual would be compelled to overuse the resource because the individual gains all of the profit but shares only a fraction of the impact felt from the degraded resource.

In his article, Hardin illustrates his point using the example of common grazing lands for herd owners. Each individual will seek to maximize their own profit from the resource, so it would be in each owner's best interest to add one more sheep to their herd. Every herd owner does the same thing, and the logic appears sound. Each individual herd owner increases their own herd, thus their profits, and every individual gains wealth. The dilemma comes when the common resource, in this case the common grazing area, becomes degraded to the point that it can no longer be used at all, and the grazing economy collapses. In fact, the herders are locked into a system that compels each individual to grab as much of the resource as possible at ever-increasing rates. In the case of the herd owners, if an individual does *not* add more sheep to their own herd, then other competing individuals will simply add more, and they will miss the opportunity to maximize utility. The hard-hitting message contained in the example rests with the recognition that it is possible for each individual to gain by acting in their own self-interest, while the group as a whole loses in the end.

This exposes a dangerous but previously unaddressed problem at the heart of capitalism and the neoliberal economy. One of the fundamental tenets of neoliberal economy assumes that all actors seek to maximize their own utility and should behave accordingly, and this is the basis of rational actions. But, if all actors behave rationally, then they will seek to maximize their utility in the market, even as the resources upon which the economy depends become degraded then depleted, and eventually disappear completely. This leads to total economic and ecologic collapse, precipitated by the destruction of the common pool resources. Hardin applied this logic to the threat of overpopulation, viewing the planetary carrying capacity as the commons, and each new person to feed as a new drain on the common resources of the planet, and concluded that there is no technical solution to this dilemma. In his analysis, Hardin separated out those problems that might have a technical solution, or a change in the techniques or science applied to them, from other problems for which there is no technical solution; this latter category requires a change in our morality or human values to find a solution.

Critics of Hardin, most famously Elinor Ostrom and colleagues, point to counterexamples where a tragedy of the commons was avoided and suggest that it is not as prevalent or as inevitable as Hardin would have us believe. She and other critics point to examples in which cooperative behavior results in collective restraint and sustained use of resources, since it is understood that not only individuals but also the collective benefit from this action. Others criticize Hardin for being historically inaccurate by failing to acknowledge the demographic transition or to distinguish between common pool resources and open access resources.

The tragedy of the commons metaphor aptly illustrates that through unlimited access to common resources, unlimited demand in a world of finite resources leads to over-exploitation. Hardin's theory sparked debate in circles of thought as wide and seemingly unconnected as game theory, psychology, cultural anthropology, and strategic model building, as well as its more obvious links to environmental studies, geography, political science, ecology, and economics. The theory stands as an easily graspable conceptual model for a wide array of resource-related and environmental issues based on the dilemma of finite resources such as water, forests, fossil fuels, and arable land, for which we seem to have ever-increasing numbers of users.

Common Pool Resources

Common pool resource theory suggests that the tragedy of the commons is not inevitable, and under specific conditions or scales, natural resources can be successfully and sustainably managed. Common pool resources, by virtue of their characteristics or size, are expensive or impossible to exclude people from obtaining benefits by using them. Resources such as the air we breathe, or the oceans, rivers, forests, pastures, and most coastal fisheries all fit this classification. If people cannot be excluded from using the resource, then management clearly becomes problematic, but in situations where conditions such as clearly defined boundaries, collective agreement on use, effective monitoring of violators, and effective conflict-resolution mechanisms exist and function well, the chance of sustaining the common pool resource goes up considerably. Ostrom developed a set of requirements needed to achieve

adaptive governance that involves sharing of information, dealing with conflict, creating responsibility among users of a resource for monitoring it, and developing a flexible infrastructure that can address errors and adapt to changing conditions. It should be noted that there are examples of successful management of common pool resources, but only at local scales, with specific resources. This does not lessen the success of the management regime. It does suggest that common pool resources will resist any unifying theory of management and may need to be addressed on a case-by-case basis according to the characteristics of the resource and the users. Critics point out that any management regime will likely become less accurate and meaningful at higher scales of governance. But the number and variety of local traditions of successful self-management or small-scale management of common pool resources do show convincingly that users do not inevitably overexploit natural resources in the absence of either privatization or regulations.

Gaia Theory

Developed by the scientist James Lovelock and the microbiologist Lynn Margulis in the 1970s, *Gaia theory* suggests that the biotic elements of Earth interact with inorganic elements of our environment to form a self-regulating interconnected system that contributes to maintaining the conditions for life on the planet. Named after the Greek goddess Gaia, this concept, also known as the *Gaia principle* and *Gaia hypothesis*, suggests that organisms coevolve with their environment. In other words, biota influences aspects of their inorganic environment, such as temperature or atmospheric conditions, and the altered environment in turn influences the development of biota, and together, these forces generate a stable system described as a *planetary homeostasis*. The interactions are complex, but here are two simplified examples used in Gaia theory: air temperature and atmosphere. Since the beginning of life on planet Earth, there has been a 25% increase in the amount of heat from the sun, but the surface temperature has remained virtually constant. Also, our atmosphere consists of roughly 79% nitrogen, 20.8% oxygen, and 0.03% carbon dioxide (CO₂). This highly unstable mix of reactive gases could

not be maintained without constant replacement and/or removal by the Earth's biota. Earlier in Earth's history, the atmosphere contained higher levels of CO₂, and these CO₂ levels produced a greenhouse effect that warmed the planet. Later, biota on the planet has produced increasing amounts of oxygen and methane, via cycling through oceans and rocks; these changes in the atmospheric chemistry have been maintained by evolving species. Now CO₂ is minimized by pumping down of carbon through the biota. Without the presence of greenhouse gases in the atmosphere, scientists estimate our planet's surface temperature would be approximately 19°C.

The idea of a planetary homeostasis, influenced by biotic factors, already exists and is studied by scholars from academic disciplines including ecology, biogeochemistry, and Earth system sciences. However, a unique element of Gaia theory puts forth the assessment that this homeostatic balance is pursued actively, if unconsciously, to achieve optimum conditions for life on the planet—even if external forces threaten that stability. Thus, taken to its logical conclusion, the theory implies that the biotic balance with the regulatory systems of the planet, such as oxygen in the atmosphere or salinity in the ocean, will maintain balances needed to optimize a biogeochemical balance, even if external human activity threatens that equilibrium. Gaia theorists believe that humans could find themselves one day headed toward extinction as a species, but that the planet as a whole would still remain, with its regulatory systems intact. Gaia theory essentially posits that the Earth is in some complex sense *alive* and functions as an intricately interconnected singular entity.

This theory has generated much speculation and debate across the academic spectrum, from philosophers to Darwinists. Philosophers use Gaia theory to begin asking fundamental questions about teleology, the meaning of *living*, and the need for consciousness in order to act in unison. To achieve this, reconsiderations of basic ethical values or concern for nonhuman and even nonliving components of the natural world would be required. The Gaian worldview rests on the notion of large-scale cooperation rather than competition as a driving force and simultaneously suggests that the planet's natural systems are not only interconnected but also function toward a common purpose—stabilization.

On the other end of the spectrum, staunch Darwinists critique the Gaia theory and suggest that evolutionary strategies could never account for complex interaction among nonsentient biota at such large scales. For Darwinists, there is simply no plausible way that the feedback loops Lovelock says work to stabilize the planet could have evolved. For Darwinists, some mechanism must be shown to control the processes described, and if they see no mechanism at work, they see no larger cohesive end. Gaia theory has also set off arguments among scientists about what it means to be *living*, and Darwinist critics note that since Gaia cannot reproduce itself, it fails to meet one of the key components in the accepted definition of *living* among the scientific community.

Resource Law

Resources also pose complications for the legal system. In the global East, resources typically come bundled with property rights, while in the West states, resources and property are severed. This means that property owners in the East also simultaneously own mineral rights, water rights, and forest rights on that property, while in the West, it is common for property to be owned by one person but, say, mineral rights owned by another. This is especially true with water rights traditions. In the East, *riparian law* dominates, which means that water cannot be taken out of its watershed, and only property that touches fresh water has rights to that water. In the West, *prior appropriation* is the rule, which allows water to be moved out of its watershed, and for water rights going to the first to claim them. For this reason, prior appropriation is often known as “first in time, first in right.” These divergent traditions come out of the radically different climate regimes and availability of water in each geographic region.

NATURAL SELECTION

Charles Darwin (1809–1882) and Alfred Russel Wallace (1823–1913) are the codiscoverers of natural selection; between them, Darwin is the chief theorist of the notion. For Darwin, natural selection is a principle, the principle by which each slight variation in organismal traits, if useful, is preserved. Darwin's understanding of selection as a principle is tightly bound to his methodology, one derived from the writings of the polymath John Herschel. Contemporary theorists have sought to differently determine the exact contours of natural selection, treating it not as a principle but as a kind of evolution (in some instances) and as a cause of evolution (in others). How natural selection operated among humans was of immediate concern to converts to Darwinism. In nations given to conquest, oppression and war, ones ruled by individuals given to elitism, racism, and ableism, natural selection provided an explanation, if not a justification, of the extermination of native communities in colonial contexts. It was also the source of a threat, as many elites were convinced that, back home in “civilized” countries, people with worse traits had more children. This conviction led to suspicion of humanitarian endeavors, state interventions to control the reproduction of “defectives,” and ultimately to Nazi atrocities. We stand today capable of editing genes by means of the CRISPR gene editing technology, giving us the potential to control human evolution with a precision unimaginable to the breeders of Darwin's time.

The Principle of Natural Selection

Darwin's work, *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*, aims to explain that “mystery of mysteries,” how species come into existence. Geologists of Darwin's day knew that species came into existence and became extinct at specific moments in the history of the Earth. What makes a species appear, then, is a puzzle. Respectable thinkers in Darwin's day defended creationism, the view that species come into being as a result of God's special acts of creation. Darwin aimed to defeat creationism. Species, argued Darwin, come into being through evolution by natural selection. According to Darwin, natural selection also explains adaptations, the adjustments of fit between organisms and their environment.

In the *Origin*, Darwin develops his theory in accordance with the methodology of John Herschel (1792–1871), the preeminent scientist of Darwin's day, and the one responsible for the “mystery of mysteries” remark. Darwin begins the work with a discussion of breeding in order to establish selection as a *vera causa*, that is, a genuine or “true” cause, and the right sort of thing with which to explain. *Verae causae* stand in contrast to a mere hypothesis, what Herschel would have derided as a “mere figment[s] of mind.” Having established selection as a *vera causa*, Darwin then generalizes from the specific case of artificial selection across a variety of other processes involving diminished human control to finally include selection among wild animals, that is, “natural selection,” the critical concept in Darwin's explanation of speciation and adaptation.

In his first chapter, Darwin offers an extended discussion of variations among breeds of domesticated organisms; he pays particular attention to the different races of pigeons, emphasizing the extent of the differences among them. No one thing is responsible for the variation, but Darwin attributes the bulk of the explanatory burden to human beings' power of accumulative selection: Nature gives successive variations; humans add them up in certain directions useful to ourselves. Genuine causes, *verae causae*, are ones of which

we have experience; artificial selection is a genuine cause because people are known to have used it, in domestic contexts, to produce variations as great as those that distinguish species.

Having established artificial selection as a genuine cause of differences among breeds of domesticated organisms, Darwin moves to generalize from this home case, in a stepwise fashion. Other selection practices that Darwin considers include “roguing,” the removal from seedbeds of deviant forms, and “unconscious selection,” by which breeders improve their stock by allowing only their best animals to breed, something even “savages” do. Even bans on the import of foreign animals create selection processes. Darwin ultimately extends the notion of selection to cover processes occurring among organisms in nature.

Organisms in nature vary just as domesticated organisms do; moreover, they must compete with one another in the struggle for existence (and, among sexual organisms, in the struggle for mating opportunities). More offspring are produced than can survive to reproductive maturity; those that reproduce are a selection from the pool of candidate reproducers. The struggle to join the pool results from checks on population increase, in the form of resource limitations, predation, disease, harsh climate, and innumerable other causes of differential reproduction on the part of population members. Many of these causes affect who makes it into the pool of reproducers by simply killing their rivals off. Any heritable variation conducive to success in this struggle will tend to be preserved, “selected,” leading to the accumulation of profitable variations across generations and ultimately to the evolution both of new species and adaptations.

In the *Origin*, Darwin offers imaginary illustrations of this process, the most famous of which involves a population of wolves that evolve adaptations for increased speed that allow them to better catch their fleet prey. Scenarios such as this one aim to exhibit how the theory works; Darwin’s wolf scenario shows how to use the theory to explain. Since Darwin’s time, there have been a great many applications of his theory to real-world systems, from cichlid fish to water snakes, to side-blotched lizards. Naturalists make genuine

explanatory deployments of evolutionary theory. But Darwin’s illustration is not meant to be an actual explanation of how wolves evolved. As noted earlier in this entry, Darwin aimed to explain the origin of species, but Darwin did not make a catalog of explained bouts of evolution, as though to explain all of them, one by one. The world is vast; its history, long. The diversity of life is great and its historical record is sketchy. Explaining the origin of species does not mean actually explaining every instance of evolution ever, at least not in the rigorous manner that researchers have done for cichlids, snakes, lizards, and countless other cases.

Darwin showed how speciation and adaptation *could be explained*, without appeal to supernatural causes. The case for creationism rests in part on the contention that designed-appearing features of the universe, adaptations and speciation events in geologic record, cannot be explained without appeal to supernatural causes. William Paley, whose reasoning Darwin much admired, inferred the existence of a designer on the basis of the complexity and functionality of natural forms. The theory of evolution by natural selection supplies us, to this day, with a framework that makes speciation and adaptation explicable, both scientifically and naturalistically. Darwin showed us how we may rationally resist the creationist argument that the origin of species and adaptations cannot be explained without a designer; rather, even the most seemingly complex and functional of organismal traits are explicable in terms of evolution by natural selection.

Selection as a Kind of Evolution

For Darwin, natural selection is a notion he is dedicated to securing as a genuine cause. He aims to do this by means of a generalization, one starting from artificial selection. Rather than emphasizing the distinguishing features of natural selection, Darwin is especially concerned to connect it with artificial selection under the broader rubric of selection *tout court*. More contemporary theorists have been much concerned, however, with the distinguishing features of natural selection.

In Darwin's wake, theorists have been concerned to specify the domain of application of his theory. Different writers have contended that evolutionary theory applies more broadly than Darwin initially envisaged, prompting the question of how to precisely state the scope of its application.

In a couple of separate publications, Richard Lewontin (1970, 1978) offers two differing statements of the requirements for evolution by natural selection; he aims to specify on what principles rests Darwin's theory. The first set of principles requires the heritability of fitness (Principle 3) and applies to populations:

1. Different individuals in a population have different morphologies, physiologies, and behaviors (phenotypic variation).
2. Different phenotypes have different rates of survival and reproduction in different environments (differential fitness).
3. There is a correlation between parents and offspring in the contribution of each to future generations (fitness is heritable).

The second set of principles requires the heritability of phenotypic variations rather than fitness and applies to species.

It has proven difficult for theorists to adequately state the requirements for selection. Some issues remain indeterminate. Lewontin was probably better off with requirements for evolution by natural selection that apply to populations; members of any given species are sometimes too spread out to be undergoing a single selection process. But if evolutionary theory is to apply to populations, how these are to be circumscribed remains an outstanding issue.

Statements of the requirements for selection also must face borderline cases and seeming counterexamples. Populations in which fitness is not heritable, but in which variants have different mortality rates, will evolve from an even distribution of fitter and less fit types to a stable polymorphism in which the fitter types are more frequent. This is simply because their death rate is lower. This sort of evolutionary change at least looks a lot like evolution by natural selection, though it doesn't meet Lewontin's conditions. Similarly, especially heritable variations will spread in a

population despite not being especially conducive to reproduction: Here, we have evolution by natural selection without differential fitness.

Lewontin wrote that the theory of evolution by natural selection rested on his principles. But he effectively makes evolution a feature of the systems to which the theory applies. Curiously, this may be too strong a constraint. While we might initially think to say that evolutionary theory is about evolution, that position is likely unsustainable.

The contention that evolutionary theory applies to systems that evolve is odd from a historical perspective; Darwin himself used the theory he himself developed to explain at least one polymorphism, heterostyly. Plants exhibiting heterostyly develop two, or sometimes three, different forms of flower whose reproductive organs vary in a number of ways, principally length. Darwin regarded heterostyly as a polymorphism that existed to stimulate the intercrossing of different plants. Darwin theory, at least, may explain cases of nonevolution as well as cases of evolution. Furthermore, the same population genetics equations that can be used to show how diverse sorts of populations evolve may equally be used to show how populations reach stable polymorphisms; only the values of some variables need to be adjusted. Evolutionary theory, or at very least population genetics, is widely applied to natural populations to explain polymorphisms; the stable polymorphism resulting from heterozygote superiority, or overdominance, is merely the most well-known example.

It is not just evolution together with stable polymorphisms that evolutionary theory explains. The side-blotched lizards mentioned earlier exhibit a kind of cyclical dynamics. The lizards come in three different colors and selection works against each type as it becomes more common. Ultimately, the system dynamics explicable using evolutionary theory are diverse: to cycles and stable polymorphisms, we should add protected polymorphisms and even random evolutionary change.

To see this last point, consider how, in less idealized, more "realistic" population genetics models, evolution is treated as a random process, as the result of both selection and drift. Presumably, drift is an element of evolutionary theory alongside selection; both are co-contributors to the

dynamics are any actual populations in nature. But if that is so, then just as selection-only models are a core element of evolutionary theory, drift-only models must equally be such. Indeed, much genetic polymorphism may be due to drift and mutation alone (Motoo Kimura's *neutral theory of molecular evolution*) or almost due to drift and mutation alone (Tomoko Ohta's *nearly neutral theory of molecular evolution*). Indeed, Lewontin himself, along with Stephen Jay Gould, critiqued the adaptationist program dedicated to explaining all traits as adaptations that evolved from natural selection; other mechanisms, including drift along with developmental and phyletic constraints, play important explanatory roles.

Conditions for evolution by natural selection, then, whatever their function, will not suffice to state the conditions of application of a contemporary scientific theory, since the theory that covers evolution by natural selection explains more than just evolution and does so in terms of more than just selection. Other theorists, equally concerned with the scope of evolutionary theory, have approached stating the conditions of its application by means of the notion of replication. Richard Dawkins's *The Selfish Gene* will forever be remembered for pioneering the term *meme*, that is, a unit of cultural information that spreads by imitation, much as genes spread by copying. Dawkins, together with David Hull, singles out active germ-line replicators as crucial to triggering the application of evolutionary theory. Active replicators influence their probability of being copied while germ line ones have potentially infinite lives in the form of copies; nonneutral genes found in gametes are the paradigm, but not sole, cases of such replicators.

Critics of replicator selectionists have countered that copying is not, in fact, necessary for evolution by natural selection; similarity between parents and offspring is sufficient. (Darwin, for his part, knew nothing of replicators or genes and grew to emphasize the importance of continuous variation in later editions of the *Origin*.) Equally, it is arguable that a gene need not be a germ-line replicator in order to undergo selection; in the immune system, a selection process determines cell frequencies. Indeed, theorists have invoked selection processes to explain phenomena even further afield, including quantum mechanics.

Selection as a Cause of Evolution

Recall that, at the end of the discussion of Lewontin's conditions, we considered how cases of random evolution, ones *without selection*, belong within the purview of evolutionary theory. Indeed, this was a point made using the notion of selection and contrasting it with *drift*. So there is at least one other ordinary usage of the notion of natural selection, outside Lewontin's conditions, that applies to a component of the evolutionary process: Selection contributes to determining the dynamics of natural systems but does so along with other phenomena, including mutation, migration, segregation, and drift, where each of these is quantified separately in formal models of system dynamics. On this approach, selection is quantified by fitness coefficients, while other phenomena (how inheritance works, which types of descendants are produced by which types of ancestor, etc.) are captured other components of formal models. Selection here is *distinguished* from inheritance and reproduction, rather than being brought into being (in part) by these, as in Lewontin's conditions (recall that Lewontin included among his principles of evolution by natural selection heritability and descendant production). When "natural selection" is used to mean *that which is quantified by fitness coefficients*, selection is being treated as a cause of type frequencies, rather than as a kind of evolution, as it is for Lewontin. Indeed, while a system governed by equations featuring fitness variables may be said to undergo selection for this reason, this by no means guarantees evolutionary change, even when the fitness variables take different values. A multitude of systems of equations with variant fitness variables determine stable polymorphisms.

Historically, population genetics models of selection have undergone a history of complexification. Early models were simple and, importantly, analytically tractable, beginning with the simple case of two alleles at a single locus. Theorists have since developed ever more complex models suitable for ever more diverse systems, often labeling the newly considered systems and associated models as ones undergoing types of selection. So, we get gametic selection models (for segregation distortion), multilocus selection

models (of variable number of loci), frequency-dependent models (with any variety of function determining fitness values), and variable selection models for different sorts of population structures, to name just a few.

Consider, in particular, spatially variable selection models. These are suitable for systems in which at least one nondegenerately distributed environmental cause interacts with the variant types distinguished in the population. (Two causes interact when the influence of at least one is a function of the value of the other.) The conditions that trigger the application of variable selection models can be stated rigorously, as we did just now, using the same language that is used in quantitative causal modeling elsewhere in the sciences. This restatement condition extends to the rest of the different types of selection. Fitness coefficients are, in the end, coefficients. They quantify the extent of a dependency. In evolutionary theory, they quantify the dependency between being an entity of a particular type and contributions to subsequent generations. Sometimes, this dependency is environment specific in a variable environment, triggering the deployment of systems of equations for population members distinguished by environment *and* genotype (spatially variable selection models); sometimes, this dependency is specific to what other members co-occupy the population (frequency-dependent selection models); sometimes, this last dependency is specific to subgroup (as in group-selection models); and so on. These are different types of selection in name only; the deployment of the associated models is triggered by interactive causes in the causal context of the population.

Darwinism in Historical Context

Darwin's *Origin* was widely read. He drew readers' attention to the potential for evolutionary change in populations, driven by differential rates of reproduction. Even though Darwin would not himself publish *The Descent of Man* until 1871, readers of the *Origin* could hardly fail to wonder which human beings reproduced the most and what evolutionary consequences could be expected as a result.

Thinkers in Darwin's wake were concerned with natural selection among human beings in

two different contexts. The first was the colonial one. Darwin and his contemporaries regarded native peoples as uncivilized, even animalistic, in comparison to Europeans. Europeans were liable to see interactions between themselves and native populations as one-sided competitions between populations. Europeans thought themselves destined to win these contests at the expense of the "savage" races by virtue of their superior moral, intellectual, and physical qualities. The extirpation of native communities was seen as an inevitable, if for some regrettable, consequence of natural selection in the colonial context.

Though a history of evolution by natural selection accounted for the prevalence of socially valuable traits among Europeans (at least as far as they themselves were concerned), Victorians saw themselves as threatened with an evolutionary reversal within their own societies, one that resulted from the greater reproduction rates among the poor. In his 1865 essay, "Hereditary Talent and Character," Francis Galton, Darwin's cousin, argued that human traits relevant to success in society, that is, cognitive, moral, and personality traits, were transmitted from human parents to their offspring. Galton and his contemporaries were convinced, on scant evidence, that the poor and other undesirables—the social residuum—reproduced more than did the higher classes, whose members were, on the whole, more valuable to society. The purported preponderance of unfavorable traits—diminished intelligence, moral character, and industriousness—among those who reproduced the most sparked a widespread worry about decline, one driven by the elitist, ethnocentric, and racist attitudes commonplace in the era. Concerns were especially pronounced given the competition in Europe among rival imperialist nations; a great many British men recruited to serve in the Boer War were rejected as being unfit for military service, something that was taken as evidence that Britain was in decline.

This decline was exacerbated by modern medicine along with humanitarian measures that prevented the elimination from society of the weakest in physical, mental, and moral capacities. Indeed, the moral sentiment to help the desperate presented something of a special difficulty, since the prevalence of such sentiments marked the superiority of European populations over the beastly

savages and yet also threatened that superiority. Even the tendency, on the part of the prudent, to delay marriage and child-rearing until such a time as children could be properly cared for had regrettable, “dysgenic” consequences for the population. Still, Darwin emphasized how, nevertheless, selection remained in some ways a positive force within industrial nations: It improved the body and intellectual capacities, even among the poorest classes. Moreover, those with the worst dispositions were unlikely to foster many children: criminals and the insane got locked up; the violent tended to die violent deaths themselves.

Darwin never advocated for state control over reproduction but was equally not optimistic that the reckless could be persuaded to have fewer children and the gifted, more. By the turn of the 20th century, attitudes had hardened. “Defectives” were segregated to prevent their having children; unconsented sterilization of the same people, a cheaper method of control, was adopted in many European countries and parts of the United States and Canada. No country was more intent on controlling reproduction than Germany; indeed, sterilization programs existed in Germany alongside ever more brutal methods of achieving “race hygiene”; the practices of extermination of criminals and defectives paved the way for the horrors of the Nazi regime.

Eugenics will forever be associated with Nazi atrocities. But our contemporary society lies on the cusp of instituting some very strong selection pressures again human genes, although not by means of coercive, state-level control over which humans have how many children. Direct genetic manipulation of the human germ line is no longer the purview of science fiction, thanks to the recently developed CRISPR technology. Good riddance, say some, to such genes as the one that causes Huntington’s disease; others see a dark future of unequally distributed genetic enhancements. Medicine, once credited with having stalled selection in human societies may soon become a forum for its most exacting application yet.

Laissez-faire opponents of government intervention could find support for their views in Darwin; Darwin himself wrote in the *Descent of Man* that no one could doubt that humanitarian practices were highly injurious to the race of man. But, perhaps surprisingly, thinkers of many political persuasions found support for their positions in

Darwin. Religious skeptics, often political radicals rather than conservatives, appealed to the *Origin* to bolster their opposition to religion. Opposition to war, in which especially a great many fit young men died, could equally be opposed for its deleterious evolutionary consequences. Darwin thought subjugation women’s natural station, but feminists could appeal to Darwinian principles in defense of their views, too. Diminished power and standing for women in society reduced the power of sexual selection to improve the human race: Too many women were forced by their social circumstances to settle for, and have children with, inferior men.

Efforts to make rigorous the notion of natural selection may have outlived their usefulness. The concept is ultimately traced to a theory developed by Darwin to demystify adaptation and speciation, but its initial narrow focus has fallen away. Speciation and adaptation were so important to Darwin because they were mysterious. But what Victorian-era Europeans found mysterious, and what results from a distinct type of process in nature for which there is a definite, particular special scientific theory, are obviously different things. What selection could explain was always going to be more than its initial explanatory uses. So the theory that Darwin used to explain adaptation and speciation could perhaps never have been expected to stay put to explain only within a given purview and only with particular tools. The history of the development of evolutionary theory is one of complexification and expansion. Adjacent to every type of population, ideal or real, that has been modeled by some or another evolutionary theorist is another natural system, just a little bit different, that may itself be modeled by a suitably modified version of the model used for its neighbor. Even features of the environment are now said to persist by means of the process of niche construction, in which organisms modify how natural selection operates upon their populations. A theory that grows by means of iterative extensions and complexifications is not naturally confined to a specific domain; its vocabulary is not a natural target for lapidary regimentation. Given the peculiar history of Darwin’s theory, what exactly counts as natural selection may be neither be determined nor determinable.

and neuropharmacology. In the past, neuroscience was mainly associated with biology; nowadays, it is a dramatically growing multidisciplinary area that involves fields as diverse as linguistics, computer science, medicine, philosophy, engineering, physics, and psychology, among others.

Background

Although the way neuroscience is perceived nowadays is connected mainly with the scientific achievements of the 20th and 21st centuries, the origins of neuroscience date back to ancient and even prehistoric times, with the first known trepanation (perforation of the skull) having been conducted as early as the Neolithic era. Apart from its medical dimension, the brain was also the topic of consideration among ancient philosophers. For example, those interested in the philosophy of mind (e.g., Plato) studied the relation between body and mind. During the 18th and 19th centuries, phrenology, which focused on the purported relation between the measurements of the skull and one's character, was popular. Although recognized today as a pseudoscience, phrenology represents the growth of interest in the brain and its relation with other functions of the human body. The most visible progress in neuroscience took place in the 20th and 21st centuries, characterized by significant technological and technical advancements. As in the other fields of science, the development in technology has led to more sophisticated methods of research. Nowadays, neuroscience relies on—for example—magnetic resonance, ultrasonography, and radiology in studying the ways in which the brain and the nervous system function. Moreover, by applying invasive or noninvasive diagnostic methods, neuroscience provides information on the neurologic performance of healthy and unhealthy subjects. Patients whose disease or injury makes invasive methods impractical can often be diagnosed and treated by noninvasive methods. In addition, the rapid and sustained growth of the internet has contributed to knowledge awareness and innovation diffusion of neuroscientific achievements, with online scientific databases, social networking tools, and email enable effective communication among neuroscientists.

NEUROSCIENCE

Neuroscience is a field of investigation devoted to the observation of how the brain and the other components of the nervous system function, with a particular focus on their role in the cognitive, affective, and behavioral performance of an organism. Neuroscience includes many domains of research, being interrelated with such disciplines as neurobiology, neuroanatomy, neuropathology,

Areas of Research

Neuroscience's focus can be further categorized by taking into account the anatomical and functional attributes of the nervous system. Regarding anatomy, the central nervous system (CNS) and peripheral nervous system (PNS) are researched. The CNS consists of the brain and the spinal cord; the PNS is composed of spinal and cranial nerves. Considering functional classification, the autonomic nervous system is responsible for the nerves in smooth muscles and glands, whereas the somatic nervous system provides nerves to skeletal muscles and the skin. Studies of the brain do not only concentrate on how a given part of the brain is responsible for motor functions, visual perception, and verbal performance but also how the injury or illness of a given brain part leads to disorders and affects the whole performance of a person. Moreover, neuroscientists focus on the brain's performance during activities and sleep. Neuroscience also concentrates on mental illnesses (such as, e.g., schizophrenia), phobias (e.g., agoraphobia, or fear of open spaces; aviophobia, or fear of flying; arachnophobia, or fear of spiders) as well as eating or sleep disorders. Another field of interest is the notion of sensory systems, investigating the organs of taste and taste transduction. As for the visual sense, neuroscientists research, among other topics, how images are formed by the eye, how motion is perceived, and how colors and images are detected. Neuroscientists are also interested in the change of the nervous system throughout one's life, studying the changes in the brain from the embryonic stage until old age. Thus, neuroscience facilitates the understanding of the human body, its ordinary performance as well as different types of dysfunctions or problems. Neuroscience can also be subcategorized by taking into account the level of analysis in use. There are different specialties within neuroscience, such as molecular neuroscience, systems neuroscience, computational neuroscience, behavioral neuroscience, cognitive neuroscience, and clinical neuroscience, to mention a few. Starting from the smallest elements of investigation, such as molecules or cells, *molecular neuroscience* as well as *cellular neuroscience* can be researched; a more macro approach is represented by *systems neuroscience*, which benefits from the achievements in neuroscience and

biology in studying neurons and their circuits and networks. *Computational neuroscience* focuses on constructing the models of brain function by using mathematics and computer studies. Neuroscience also contributes to the understanding of individuals' behavior, cognition, and emotions. When one wants to observe the behavior of human beings, *behavioral neuroscience* offers the investigation of gender or age differences. *Cognitive neuroscience*, on the other hand, facilitates the understanding of people's emotions or reactions. To narrow the scope of the research, neuroscience may concentrate on one aspect of one's behavior. For example, *affective neuroscience* focuses on the neural side of emotions, by studying the behavior of human beings or animals. *Developmental neuroscience* observes the changes in the brain and its growth, whereas *clinical neuroscience* focuses on neurological disorders and brain injuries and involves treating patients in hospitals and other specialized health centers.

Regarding the scope of investigation, neuroscience focuses on both the smallest and the biggest entities responsible for the functioning of the brain and the nervous system. Taking into account the smallest elements of neuroscientific investigations, the neuron is one of the key components studied by neuroscientists. This type of cell is found in the bodies of human beings and almost all types of animals. Neurons possess the zones called synapses that enable them to communicate with other neurons, mainly by chemical neurotransmission. The studies on neurons and their electrophysiological properties facilitate the understanding how such complex systems operate and the way human bodies function. In addition, neuroscientists are interested in, for example, the parts of the brain, such as the cerebrum, consisting of frontal lobes, parietal lobes, temporal lobes, and their role in how a body functions. At the same time, neuroscientists look at the body as a whole since the health problems characterized by neurological symptoms, such as headaches, speech disorders, and numbness of limbs may have their roots in some dysfunction of one of the bodily organs, not necessarily the brain.

Neuroscience and Other Disciplines

The vast scope of issues and the complexity of the brain and the nervous system make neuroscience

crucial for the development of other areas of study. Taking into account the role of communication and language for human beings in social contacts, neuroscience is crucial to the sphere of language. The interrelation of these fields of investigation has given rise to *neurolinguistics*, which focuses on such topics as linguistic preferences, bilingualism, and multilingualism. In addition, neurolinguists are interested in language-related neurological problems or illnesses, such as aphasia, dementia, dyslexia, and dysgraphia. Thus, the research is devoted to how languages are perceived, learned, and used, taking into account language understood in different ways. Thus, not only languages understood as the official languages shared by a large group of people (e.g., a nation) are investigated, but also professional discourses, dialects, and genres are studied. Consequently, the learning and teaching processes are researched by studying, for example, mother tongues, foreign languages, and minority languages. Taking into account the example of linguistics, the subdisciplines of neuroscience can be characterized by interrelations. Since a language does not exist in a vacuum but is an important element of other fields of research, neurolinguists may work together with neuromarketers, studying the neurodimension of linguistic branding or advertising, or researching how customers select products and services on the basis of the offered linguistic information or stimulus. In the case of *neuromanagement*, this field may provide knowledge of how language is studied in professional settings, with observation of the role of language policies and the type of management as such. Moreover, *neuroethics* analyzes how the used linguistic tools strengthen, say, the policy of corporate social responsibility. Neuroscience is also crucial for education, leading to the appearance of such disciplines as *neuroeducation* or educational neuroscience. In addition, such subfields as neuropedagogy, neurodidactics, neuroteaching, and neurolearning can be named. Moreover, those working in education can also benefit from the knowledge of other domains relying on neurostudies, such as neurolinguistics, neuromanagement, neuroeconomics, cognitive neuroscience, cultural neuroscience, social neuroscience, and neuropsychology. Another field of investigation, *neurobiology*, is more focused on the biological

aspects of brain performance and thus, in the case of linguistics, can provide additional information on the part of the brain and its role in linguistic performance. Neurobiology can also be useful in clinical and therapeutical treatments, helping people recovering from brain injuries or facing some health problems to regain their speaking abilities. Neuroscience can also be used in studying the nature of art and beauty. *Neuro-aesthetics* focuses on studying aesthetics by means of neuroscientific methods and approaches. Such investigations offering information how art and music are perceived and experienced are of importance not only for neuroscientists but also for artists, historians, and those participating in the art life.

Neuroscientific Research

The issues of interest in neuroscience can be studied through the *4R model of neuroscientific research*, which focuses on the societal, behavioral, cognitive, and biological dimensions of one's performance and thus can be grouped around four main fields of investigation: Recognition, Reaction, Remembering, and Relations. The model, created by the author of this entry, is presented in Figure 1.

Figure 1 4R Model of Neuroscientific Research

Recognition

Neuroscientists are interested how individuals recognize and perceive reality. One of the aims is to study how the brain and the nervous system take part in various behavioral and cognitive activities. Topics of study include the features of entities that make them attract the attention of subjects. Among the types of research available in the literature are those that focus on the role of colors, words, and images in capturing the attention of individuals and enabling these features to be recognized and categorized. Taking the linguistic type of study into account, research may focus on the role of metaphors in describing novel and complex concepts and recognizing their meaning. In addition, recognition can be studied by taking into account cultural differences in recognizing different concepts. For example, a figure from a fairy tale may be unknown in a culture that is not acquainted with a particular story. Thus, using this cultural concept in international advertising may be ineffective insofar as it requires familiarity with a culture-specific motif.

Remembering

Neuroscience offers explanations for how people perceive, acquire, store, and later apply knowledge. For example, the role of presenting data is studied, and its implications for understanding and using novel concepts are given close consideration. As far as neurolinguistic studies are concerned, researchers are interested how literal and nonliteral expressions are understood by individuals and which of them are more easily remembered. In addition, the neuroscientists study the role of repetition in learning new things as well as storing in memory the information already acquired. Another field of investigation is the nature of processes in short-term and long-term memory. Scientists are also interested in the role of representation in storing and using novel data. For example, they investigate the role of verbal and nonverbal stimuli in understanding new information. Research may involve studies of how pictures and sounds may facilitate the understanding and memorizing of information. Such findings are applicable, for example, in education, guiding teachers in how to choose materials to make

learning processes more efficient; and in neuro-branding, guiding marketers in how to make a brand remain longer in the minds of customers. Those interested in memory also take into account how different factors determine the possibilities of storing knowledge. For example, such factors as age and gender may be used to study people's differences in perceiving and memorizing data, thus forming a basis for the provision of diversified materials by taking into account the differing abilities of users. The study of people with memorizing deficits offers information as to which methods may prove most useful in teaching individuals having problems with perception and memorization, such as those with dementia or Alzheimer's disease.

Reaction

Reactions may be studied by observing subjects' responses to a presented stimulus. Such experiments involve the presentation of verbal and nonverbal cues and observing and measuring the reply to the incentives. These types of experiments are especially popular in marketing since they allow to study how people perceive a product or a service and what reactions follow the exposure to a given brand. Neuroscience is also interested in what makes reactions different from person to person, and the implications for evoking responses, both voluntary and involuntary. In addition, reactions may be studied by taking into account one's deficits as well as absent or exaggerated response to a stimulus. Also of interest are the ways in which some substances influence people's reactions. For example, neuroscientists investigate how alcohol, nicotine, medical substances, herbs, or narcotics may affect the performance of the brain and the nervous system. Such studies may develop the knowledge in the field of addictive substances to observe how certain substances may have deleterious effects on the brain and other organs. On another front, those interested in nutrition may be provided with more detailed information concerning proper diet and the influence of various foods on motor, cognitive, and behavioral functions of a human body. Proper nutrition becomes especially important for children, seniors, and people with illness since all have specific nutritional needs according to category.

Relation

Neuroscience facilitates the understanding of internal and external relations. Taking into account *actor–network theory*, neuroscience facilitates understanding about the role of human beings and nonliving entities in shaping reality. Neuroscientific tools offer information about the relation between different elements and their role in the overall performance of a given entity. Observing this feature in the linguistic domain, neuroscientists may investigate which sentences or words determine the efficient perception of a text. Another language-related issue may be studied by examining the role of literal and nonliteral elements in making a piece of information more easily understood by a diverse audience. Apart from the subject approach, neuroscience may also study human relations. By examining, for example, one's response to a given social stimulus, the role of interaction with other individuals may also be investigated. In addition, neuroscience facilitates the understanding of relations between neuroscience and other domains of knowledge—for example, neurolaw, neurolinguistics, or neuromanagement—which, at the same time, contribute to other domains of science and benefit from other disciplines.

Approaches and Tools Used in Neuroscience

Neuroscience relies on different methods and devices in conducting neuroscientific experiments. One possibility of categorizing them is to take into account the function they have. Thus, it is possible to discuss methodology used for scientific and clinical purposes. In addition, neuroscientific tools can be divided by taking into account the subjects. Thus, different devices are used for investigating animals and for investigating human beings. The approaches to conducting neuroscientific experiments can also be divided into invasive and noninvasive ones. Noninvasive techniques are used both for diagnosing and researching. One advanced apparatus is *functional magnetic resonance imaging* (fMRI); this neuroimaging technique relies on the phenomenon of magnetic resonance to observe brain performance. The subject lies still within an MRI scanner for about 60 to 90 minutes. The first stage takes about 6 to 15 minutes, and it is devoted

to making anatomical scans of the brain. After this phase, the subject is asked to perform some activities. Depending on the nature of an experiment (e.g., neurobranding or neurolinguistic studies), the activities may involve, for example, selecting an option, answering a question, and finding the difference between the presented options. During the execution of these tasks, the apparatus notices and measures the *blood oxygen level depending* signal that is responsible for showing which brain areas are active during a given activity. In the next stage of an experiment, the results are compared with the control scans done before the experiment itself. Neuroscientists also study facial expressions to perform noninvasive research. One such tool is *facial electromyography*, which provides information on one's emotions and feelings. Since one's face shows the emotional state, behavioral, cognitive, and affective notions may be studied by measuring the facial muscles, which are innervated by the facial nerves. For example, observing the zygomatic major muscle provides information on one's attitude to the presented verbal or nonverbal stimulus. This type of research may be used, for example, in advertising to check the reaction of the audience to a presented commercial. Another popular tool in neuroscience is *electroencephalography* (EEG). In this experiment, a set of electrodes are positioned at specific locations on the scalp of a subject. The experimenter observes the neural activities of the subject's brain when the person lies still and, for example, during exposure to light. This technique is noninvasive; however, EEG is also used as an invasive method in, for example, brain surgery—in that case intracranial EEG is used, and the electrodes are placed on the exposed part of the brain following craniotomy, where a surgical opening is made into the skull. Invasive techniques are used when it is not possible to diagnose a patient properly by using a noninvasive method. Another invasive technique, called *single-photon emission computed tomography* (SPECT), is used to determine the flow of blood to tissues and vessels. Used in neuro-oncology, SPECT offers information on the state of examined organs by using a radioactive substance and a camera. Intracranial blood vessels are studied by *angiography*, using a contrast agent and X-rays. Another dysfunction of blood vessels related to the improper velocity of blood flow in the brain can be studied

by *transcranial Doppler* (TCD) ultrasound. Moreover, neuroscience relies on psychological experiments and tools. Psychological tests are often administered in the first stage of research to help adjust and refine the neurological methods to be used. This option turns out to be especially useful in reducing the relatively high costs of conducting neuroscientific research.

Similarly, linguistic and economic types of research conducted prior to performing a neuroscientific experiment rely on such methods as questionnaires, interviews, and discourse analysis that precede, for example, fMRI. Neuroscientific experiments can also be categorized according to the different types of stimuli used by neuroscientists. Their selection depends on a number of factors, such as the age of subjects; for example, if young children take part in an experiment, audio or visual stimuli are used instead of written ones. Another factor may be the health condition of a subject. In addition, experiments involving non-native speakers of the language in which research is being conducted should take into account that language fluency may differ among the subjects. Using different neuroscientific methods also requires attention to ethics. Subjects taking part in neuroscientific testing should be informed of how the experiment will be conducted and how the information obtained in testing will then be used. In addition, people should be informed whether the tests are invasive, and, if so, what risks are involved.

Future of Neuroscience

It can be predicted that neuroscience will foster the development of studies that currently do not rely on neuroscientific advancements. Taking into account, for example, neuromanagement and neuroeconomics and the application of neuroscientific achievements in different domains of business studies, it is likely that other fields of economic investigation will benefit from neuroscientific knowledge. One reason for the growing interest in neuroscientific methods is their preciseness and the ability to study phenomena that cannot be observed by other means of investigation. In addition, neuroscientific methods eliminate the possibility of providing fake answers by respondents. Another possible field of development in

neuroscience is connected with achievements in other domains that have a bearing on neuroscientific investigation. Thus, the ongoing advances in MRI are leading in turn to advances in neuroscientific methods. The continuing development of neuroscience will lead to progress in at least two key areas. In health care, advanced neuroscience will be more effective in curing neurological diseases and brain injuries. In addition, neuroscience will contribute to the prevention of neurological problems and aid in slowing the progress of neurodegenerative disorders, such as Alzheimer's disease. Technical advances in neurological equipment may provide quicker, more effective, and more economical methods of diagnosing patients, introducing new methods that are noninvasive. Apart from the clinical perspective, advanced neuroscience offers better understanding of social life by studying behaviors and responses to different stimuli present in everyday life. Neuroscience may offer the answer how to make communication more effective and consequently make the health care discourse easier and more beneficial for patients, families, and professionals.

P

PARACONSISTENCY

Paraconsistency is the study of logical systems with a nonexplosive negation such that a pair of contradictory formulas (with respect to such negation) does not necessarily imply triviality, discordant to what would be expected by the contemporary logical orthodoxy. From a purely logical point of view, the significance of paraconsistency relies on the meticulous distinction between the general notions of *contradictoriness* and of *triviality* of a theory—respectively, the fact that a given theory proves a proposition and its negation, and the fact that a given theory proves any proposition (in the language of its underlying logic). Aside from this simple rationale, the formal techniques and approaches that meet the latter definitional requirement are manifold. Furthermore, it is not solely the logical–mathematical properties of such systems that are open to debate. Rather, there are several foundational and philosophical questions worth studying, including the very question about the nature of the contradictions allowed by paraconsistentists. This entry aims to advance a brief account on some distinct approaches to paraconsistency, providing a panorama on the development of paraconsistent logic.

Paraconsistent Logic

From a structural standpoint, it can be said that paraconsistency is the property of a consequence relation $\vdash$ for which the principle *ex contradictione*

[*sequitur*] *quodlibet* (from a contradiction, anything [follows]) does not hold in general; that is, $A, \neg A \vdash B$ is not always the case (for a given negation $\neg$ and arbitrary propositions A and B). Accordingly, one can simply say that a logic is paraconsistent if and only if its consequence relation is not explosive.

Some other definitions of paraconsistent logic can be found in the literature. However, all of them can be shown equivalent with the latter when appropriate qualifications about the properties of the underlying inference relations are considered. Thus, a brief account on the development of such systems is appropriate.

The Beginnings (Modern Era)

The study of logical systems underlying possibly contradictory theories had risen about the same time that the constitution of the logicist and formalist schools in the philosophy of mathematics, at the end of the 19th century and the beginning of the 20th century. Indeed, already in 1910, Jan Łukasiewicz proposed a criticism on distinct formulations of Aristotle's views on contradiction. Following an equivalent route, in the same year, Nicolai A. Vasiliev advanced a kind of reasoning free from the laws of excluded middle and contradiction—called *imaginary logic* as an analogy with Nikolai Lobachevsky's *imaginary geometry* (a non-Euclidean geometry aiming to investigate the independence of the postulate of the parallels). Albeit endowing characteristics of a paraconsistent logic, namely criticizing the principle of noncontradiction, both works would mark

the birth of two other kinds of well-studied nonclassical logics—notably many-valued logics and dialectical logics, respectively.

Other works that pioneered the development of paraconsistent logic also adhere to a many-valued approach. The *logic of nonsense*, introduced by Sören Halldén in 1949, aimed at studying logical paradoxes by means of three-valued logical matrices, closely related to the *nonsense logic* introduced by Dmitrii A. Bochvar in 1938. An analogous approach was made in 1966 by Florencio G. Asenjo in his *Calculus of Antinomies*, which introduces a formal framework for studying antinomies by means of three-valued Kleene's truth tables for negation and conjunction, where the third truth-value is distinguished.

The Rise of Paraconsistent Logic as a Discipline

The contemporary growth of paraconsistent logic came about with translations of the first papers into English and an increase of interest in them. Some advancements that had marked the emergence of paraconsistent logic as a discipline, pushing forward novel results, include the works of Stanisław Jaśkowski and Newton da Costa, who independently developed comprehensive systems explicitly focusing on avoiding triviality by restraining the explosive character of contradictions, precisely the major characteristic of a paraconsistent logic—a term coined by Francisco Miró Quesada in a personal letter to da Costa in 1975, and then made public at the Third Latin America Conference on Mathematical Logic in 1976. The term *paraconsistency* is formed by the prefix *para-*, meaning “further than,” “beyond,” or even “similar to,” or “quasi”; and *consistency*, meaning the property of a system that is nontrivial or noncontradictory—two classically equivalent notions whose separation lies at the heart of the paraconsistentist agenda.

According to Jaśkowski, there are three main conditions that a contradictory yet nontrivial theory must satisfy: (1) it must be nonexplosive; (2) it should be rich enough to enable practical inference; and (3) it should have an intuitive justification. These latter two conditions, less formal than the first one, capture the biggest challenge to a paraconsistentist—namely the necessity to show that a certain account of logical consequence is somehow concerned with actual situations of reasoning.

Jaśkowski's motivation for advancing in 1948 the so-called *discussive logic* was a puzzling situation posed by Jan Łukasiewicz (of whom he was a disciple): Which logic applies in the situation where one has to defend some judgment A, also considering its negation for the sake of the argument? The strategy followed by Jaśkowski was to avoid the combination of conflicting information by precluding the rule of adjunction, making room for A and $\neg A$ without entailing the conjunction of both ($A \wedge \neg A$) since the classic explosion actually still holds in the form of $A \wedge \neg A \vdash B$. In terms of reasoning, it has a straightforward meaning: Each agent must still be individually consistent.

For da Costa, the focus is the development of systems that, on the one hand, could be strong enough to capture most of mathematics and, on the other hand, could circumvent some of the well-known paradoxes that historically had marked studies in logic. Da Costa's main intuition in the so-called *C-systems*, advanced in his 1963 paper “On the Theory of Inconsistent Formal Systems,” is that it is possible to differentiate inconsistent sentences from consistent ones or, in his own words, from those with a *well-behavior*—the latter being a sufficient requisite to guarantee the explosive character of a given formula.

Several other works in the literature arguably contributed to the development of paraconsistent logic as a mature discipline, most of them serving as a formal basis for particular research programs around which distinguished schools of paraconsistency have been organized. A brief account of those works is given in the next section from the standpoint of their respective approaches to paraconsistency.

Main Approaches to Paraconsistency

Preservationism

Out of the first works of Raymond Jennings and Peter Schotch on modal semantics, the early 1980s saw the organization of the preservationist school of paraconsistency, focused on advancing formal tools and intuitive justifications to capture the reasoning of human beings when faced with inconsistent data. Some of the core motivations include dealing with the concepts of belief and obligation, as well as C. I. Lewis's notion of *strict*

implication. Roughly speaking (apart from technical details and philosophical questions), given an inconsistent collection of sentences (in an already defined logic, usually classical logic), one should not try to reason about that collection as a whole but rather to focus on internally consistent subsets of premises. For introductory readings on the subject, see Schotch et al. (2009).

Adaptive Logics

A logic is said to be adaptive if it adapts itself to the specific premises to which it is applied. Developed out of the early work of Diderik Batens, adaptive reasoning recognizes some so-called abnormalities to develop formal strategies to deal with them: For instance, an abnormality might be an inconsistency (inconsistency-adaptive logics), or it might be an inductive inference, and a strategy might be to exclude a line of a proof (by marking it), or to change an inference rule. Thus, the paraconsistent character of the abnormality is not the main focus. Rather, the intuitive idea to be captured is that human reasoning can be better understood as endowed with many dynamic consequence relations, inconsistency-tolerant reasoning being one of them. Some papers on the subject can be found in a 2000 work by Batens and colleagues.

Relevant Logics

Mainly concerned in avoiding the paradoxes of material and strict implication, *relevant logics* are substructural logics that demand a meaningful connection between the premises and the conclusion of an argument. This strategy induces a paraconsistent character in the resulting deductions since A and $\neg A$, as premises, do not necessarily have a meaningful connection with an arbitrary conclusion B . Relevant logic evolved in the 1960s out of some early works by Alan Anderson and Nuel Belnap, themselves extending ideas of Wilhelm Ackermann, Alonzo Church, and others. For a comprehensive technical introduction, see Anderson et al. (1992).

Dialetheism

Dialetheia is a neologism formed by the Greek prefix *di[a]-*, meaning “in opposite or different directions”; and *aletheia*, a word for “truth.”

Accordingly, a *dialetheia* is a sentence that is both true and false. Developed out of the original works of Richard Routley and Graham Priest in the 1970s, mostly motivated by the advancement of tools to deal with the liar paradox and set theoretic antinomies, dialetheism is the ontological view that there are *dialetheia*, that is, the view that some contradictions are true. Therefore, as expected, the preferred logic for a dialetheist should be paraconsistent, although not all paraconsistentists are compelled to be dialetheists. For a comprehensive philosophical introduction, see Priest (1995).

Logics of Formal Inconsistency (LFIs)

A key idea here is that there are situations in which contradictions can, at least temporarily, be admissible if their behavior can be somehow controlled, as da Costa has it. Further generalizing and extending the advancements of the latter, the LFIs (as it would be christened by Walter Carnielli and João Marcos in early 2000s) are a family of logics that can encode [in]consistency within their object language, allowing an explicit separation between contradictoriness from inconsistency, inconsistency from triviality, consistency from noncontradictoriness, and nontriviality from consistency. For a state-of-the-art account of the subject, see Carnielli and Coniglio (2016).

Other Approaches

There are many ways a logic can be contradictory yet nontrivial. Jaśkowski’s discussive logic, for instance, not only followed a *nonadjunctivist* approach but also endowed a *modal* character—in fact being a fragment of the well-known modal logic S5. Another significant program is the *many-valued* one, for which the first contemporary comprehensive system with an explicit paraconsistent agenda is Asenjo’s calculus of antinomies, the same strategy followed by Priest’s *logic of paradox*, advanced in first works on dialetheism.

The fact is that there is no unique way to divide the advancements made in the literature into specific approaches, since they intersect and complement each other. Paraconsistency, as a property of logical systems, is negatively defined—it encompasses every system where *ex contradictione*

quodlibet does not hold in general. The division of those systems into distinct schools of paraconsistency, highlighting particular properties and motivations, can thus be understood solely as a pedagogical tool to introduce the rich and fruitful plurality of paraconsistent logics.

In addition to the cornerstone logic-philosophical debate, the study of paraconsistency from the perspective of finite models of arithmetic as well as the applications of paraconsistent logic in some computational areas have provided a new dimension to the ongoing debate. The fact is that since the first works in the area, paraconsistency has turned out to be a remarkably fertile research field that provides us with new ways to deal with contradictory yet nontrivial scenarios, including inconsistent theories, paradoxes, dialectics, ontology, belief dynamics, and many more.

PARADIGM

The term *paradigm* comes from the Latin word *paradigma*, which, in turn, comes from the ancient Greek word *paradeigma* (παράδειγμα: “παρα,” beside, near; “δειγμα,” sample, what is shown). *Paradigm* and cognate expressions, such as “change of paradigm” or “paradigm shift,” are used in different contexts, both scientific and academic, as well as in everyday life.

Until the appearance of Thomas S. Kuhn’s work, the word *paradigm* was used primarily in two senses: (1) in rhetoric, as an example or case of something that serves as a model or pattern for other cases of the same that may be copied; as a very clear and typical example of something, as a type-example; (2) in grammar, as an example of a conjugation or declension showing a word in all its inflectional forms, creating a pattern of conjugating or declining, where other words of the same type conjugate or decline in an analogous way.

But it is only since Kuhn’s work that the term *paradigm* and related expressions have acquired the diffusion and widespread use attained today. And although Kuhn introduces the term in the context of theoretical reflection on science, it is incorporated into colloquial language with an even more encompassing meaning, in the sense of a philosophical or theoretical framework of any kind, or in the more general sense of a perspective, a position, a view, a way of looking at something or regarding a situation or topic.

In fact, we are faced with a paradoxical situation: Although many people are familiar with the term *paradigm* and continue to use it in one sense

or another, Kuhn himself, owing to the term's ambiguity, had ceased to do so—although without renouncing the concepts that led him to its introduction. Moreover, such concepts continue to be of fundamental importance in understanding the nature, functioning, and development of science.

This entry focuses on these Kuhnian concepts of paradigm. After a brief introduction to Kuhn's paradigms, it will first place the Kuhnian conception in the context of 20th-century philosophy of science. Kuhn's concepts of paradigm will then be outlined. Next, it will be seen how these concepts explain the pattern or regularity that Kuhn identifies in the development of science. It will continue with the identification of some relations of Kuhn's proposal with classical philosophy of science. The entry concludes by pointing out some further developments of Kuhn's paradigms.

Introduction to Kuhn's Paradigms

Although the term *paradigm* is used by Kuhn for the first time in the 1959 text "The Essential Tension: Tradition and Innovation in Scientific Research," in the sense of what he would later call *exemplar*, it is with his 1962 work, *The Structure of Scientific Revolutions* (SSR), that it became customary in philosophical reflection and in historical analyses of science.

In this work, which seeks to promote a more authentically historical history of science, contra *presentism*, *whiggism*, or the *Whig interpretation of history*, Kuhn develops a theory of the history of science that opposes the received image of scientific development, which considers it to be cumulative, continuous, and linear.

This theory of the history of science has strong implications for the philosophy of science, where the philosophical importance of historiographical reform is manifested.

For, insofar as the philosophy of science is based on the history of science and forms its image of the practices and rationality of science from it, if the history of science is wrong, so will be the philosophy of science *modeled* on it.

Thus, SSR also promotes a revision of philosophers' image of science, in particular of scientific change, intending to bring philosophy of science in tune with what scientists really do, and have done, throughout history, thereby forcing us to

rethink the concepts of rationality, progress, and scientific development.

In time, SSR ended up becoming a true best seller and has marked our conception of science ever since.

The Kuhnian Conception in the Context of 20th-Century Philosophy of Science

The prevalent image of philosophers of science by the mid-20th century was that of the so-called classical conception (or *received view*) of theories and some related ideas on science around topics such as concept formation, hypothesis testing, and scientific explanation. In its most general sense, the classical conception of theories can be characterized as explicating the concept of a scientific theory as a set of statements, sentences, or propositions deductively or axiomatically organized.

By contrast, in a more detailed formulation, such as that outlined by Rudolf Carnap, we can distinguish three general aspects in the explication of the concept of theory. The first one refers to the (more) *theoretical* (or *formal*) part that is constituted by the formal axiomatic system or *calculus* (symbolized by *T*)—which contain only descriptive theoretical terms. The second one corresponds to the (more) *empirical* or *testing* part that is given by pure observational statements—which contain only descriptive observational terms. The third one establishes the relationship between *theory* and *experience* through linguistic means, the so-called correspondence rules (symbolized by *C*)—which connect theoretical terms with observational terms. Thus, *the* theory, or interpreted calculus, consists of the conjunction of all the axioms and all the correspondence rules *T* and *C*.

Beginning in the 1950s, this view of scientific theories has been subject to criticism, of which there are mainly two kinds: (a) criticisms of certain aspects of the classical conception (e.g., of the distinction between theoretical and observational terms) and (b) a global criticism, which attacks mainly the bases of the conception, proposing an alternative view on science. The second kind of criticisms of the classical conception came mainly from people interested in the history of science, once referred to as *new philosophers*, giving rise to what would be called the *historical turn* in the

philosophy of science, of which Kuhn is its best-known representative. A new conception about the nature and the synchronic structure of scientific theories (without this being implied in a strict sense and without its being systematically developed) underlies the majority of diachronic studies and analyses, typical of this historicist phase, which is supposed to be closer to scientific practice, as history presents it to us.

According to the new conception, scientific theories, which the new philosophers refer to with different terms (paradigms or *disciplinary matrixes* for Kuhn, *research programs* for Imre Lakatos, *research traditions* for Larry Laudan), in order to avoid being confused with the classical conception, are not sentences or sentence sequences, and in a proper sense they cannot be described as true or false (although true or false empirical claims are certainly made with them), but they are highly complex and ductile entities, susceptible of evolving in time without losing their identity.

But Kuhn's proposal should also be placed within another of the *turns* that have taken place in analytic philosophy in general and philosophy of science in particular, namely the so-called *pragmatic turn*. This turn in philosophy of science arises from the rejection of what Wolfgang Stegmüller calls *the third dogma of empiricism*, namely the conviction that for the explication of all epistemologically relevant fundamental aspects of science the instruments of logic (syntactic and semantic tools) are sufficient.

This led to the acceptance that in the philosophical investigation of science, not only the syntactic and semantic aspects of language but also the pragmatic ones must be taken into consideration.

It is often said that the changes that occurred in the philosophy of science during the 1960s produced a real revolution in the field. If, however, we take into account the multiplicity and variety of positions held by philosophers of science in the first half of the 20th century, it would perhaps be better to characterize these changes as a recovery or deepening of the problems addressed and of the solutions previously advanced, for example, by logical empiricists such as Otto Neurath, Edgar Zilsel, Philip Frank, or even Rudolf Carnap, or by people outside this philosophical movement, in particular Ludwik Fleck.

Nevertheless, the incidence of the new philosophers was decisive in this resurgence in the 1960s: The consideration of the historical or historicist perspective that generally characterizes them definitely marks the development of later metascientific reflection.

Kuhn's Concept(s) of Paradigm

Since the appearance of the first edition of SSR in 1962, the notion of *paradigm*, central to Kuhn's conception of science, has been critiqued for its vagueness and ambiguity. One commentator went so far as to point out 21 different senses of this term, while acknowledging that not all of them are inconsistent with each other.

Kuhn took this criticism seriously. In 1969, he wrote three works—the book chapters “Second Thoughts on Paradigms,” “Reflection on My Critics,” and a postscript for the second edition of SSR—with the aim of clarifying some points of view developed in SSR, including his conception of paradigms. In them, he claims to have been using the term *paradigm* basically in two different senses: (1) as the global set of commitments shared by the members of a given scientific community and (2) as concrete solutions to problems.

To avoid misunderstandings, he proposes to replace the term *paradigm* by *disciplinary matrix* to refer to the first, *global* sense of the term, and by *exemplars* to refer to the second, *original* sense of the term. The following are the elements that constitute a disciplinary matrix:

1. *Symbolic generalizations*, which are law schemes not discussed by scientists, formalized or easily formalized, and which act partly as definitions and partly as genuine laws, establishing the most general relationships between the entities that populate the field under investigation (and corresponding to Kuhnian explication of the concept of fundamental law).
2. *Ontological or heuristic models*, which manifest the ontological or metaphysical convictions as to what there is and what its fundamental characteristics are, and which give the group its preferred or permissible analogies and metaphors and make it possible to visualize and make its behavior more comprehensible.

3. *Methodological values*, which may be shared with other disciplinary matrixes, such as accuracy—exact agreement, or not exceeding a certain margin of error, with the results of existing experiments and observations; consistency—internally and with other currently accepted theories; scope—extending far beyond the particular observations; simplicity—bringing order to phenomena that otherwise would be individually isolated and, as a set, confused; and fruitfulness—disclosing new phenomena or previously unnoted relationships among those already known.
4. *Shared examples or exemplars*, which Kuhn considers the most original and least understood aspect of his book, and which constitutes the original meaning of the term *paradigm*, as introduced in his (Kuhn, 1959) in analogy with its use in language teaching. They are concrete solutions that successfully solve problems posed by the paradigm-disciplinary matrix, adapting the symbolic generalizations and obtaining the specific symbolic forms required by particular problems; and which show scientists in a nondiscursive way what entities populate the universe of research, what questions can be asked, what are the admissible answers, and what are the methods for testing them. Shared examples or exemplars constitute sense 2 of *paradigm*, distinguished above.

The Development of Science

The nature and function of paradigms, both in the sense of disciplinary matrix and in the sense of exemplar, explain the pattern or regularity that Kuhn identifies in the development of the mature sciences, that is, the successive phases, stages or periods—after an initial one of preparadigm (prenormal or preconsensus) science—of normal science, crisis and extraordinary science, new normal science, new crisis and extraordinary science . . . (what constitutes “the structure of scientific development” in general), and the successive transition from one paradigm to another through a scientific revolution (what constitutes “the structure of scientific revolutions” in particular).

The preparadigm (or, perhaps better, prenormal or preconsensus) period is characterized by the

existence of competing different schools and subschools working in different directions, without common commitments.

After a paradigm-disciplinary matrix achieves the consensus of the scientific community, a broad avenue for research opens up, in the form of closely related problem-solving or, insofar as they are supposed to have an assured solution within the accepted paradigm-disciplinary matrix, *puzzle-solving*, which scientists carry out under its guidance over a long period, called *normal science*. Scientists recognize the problems posed by the paradigm-disciplinary matrix as similar to the shared examples or exemplars and solve them in a manner similar to the shared examples. Through this practice, the paradigm-disciplinary matrix achieves greater precision and articulation within itself and with nature; that is, it also broadens its domain of application.

During this period of normal science, scientists work with the conviction that this or that problem will have a solution within the conceptual framework of the paradigm-disciplinary matrix, proposing, in a hypothetical manner, that a certain modification of the symbolic generalization—though not obtained by deduction (just) from it—will do the job. If the proposal of a specific symbolic form is successful, the applicability of the paradigm-disciplinary matrix to reality is extended, affirming it in its fertility. In the case of its refutation, the discredited one is, according to Kuhn, the scientist himself—who fails to propose the appropriate specific form of the symbolic generalization that would solve the problem posed, one that would satisfactorily fit the data obtained—and not the paradigm-disciplinary matrix.

Faced with a negative test, the symbolic generalization of the paradigm-disciplinary matrix is, or can be, always safeguarded by modifying the nonnuclear elements, in other words the specific form proposed by the scientist to solve the *puzzle* posed by the paradigm-disciplinary matrix and whose resolution would be assured.

However, when frustrations accumulate while trying to solve *problems* that should be solved, these go from being the driving force of the development of the paradigm-disciplinary matrix to being perceived as *anomalies* whose existence compromises the usefulness of the paradigm-disciplinary matrix for research. A period of *crisis* and *extraordinary science* begins. A small group of

researchers starts to work outside the accepted paradigm-disciplinary matrix from new perspectives that are incompatible with the previous ones, until a new paradigm-disciplinary matrix is established that succeeds in problem areas that the scientific community considers important, and promises to solve others, some of which were not even on the agenda of the previous one, and giving up others, which are now no longer considered legitimate. The bulk of the scientific community begins to abandon a paradigm-disciplinary matrix exhausted in its heuristics, to adopt the one that allows it to leave behind the feeling of futility of its own work, consummating a *scientific revolution* and giving rise to a new period of normal science.

The rupture present in the shift from the old paradigm-disciplinary matrix to the new one thus entails not only gain but also loss. Although incommensurable—meaning by this that there is no common or neutral basis with which to measure both paradigm-disciplinary matrixes or a common or neutral (observational) language that allows the intertranslatability of both paradigm-disciplinary matrixes without waste or loss—the process of abandoning one paradigm-disciplinary matrix and simultaneously accepting another is not irrational, as Kuhn's critics thought. The choice between paradigm-disciplinary matrixes is not resolved by the application of norms or rules based only on logic (internal coherence) or experiment (external coherence). This does not imply, however, that there are no good reasons guiding such a choice, rather only that these reasons (among which are the aforementioned simplicity, accuracy, coherence, scope, and the ability to generate fruitful research) function as values or criteria shared by scientists but are capable of being applied differently by different researchers—a rationality of another type (practical), different from the one traditionally proposed (logical or theoretical), but as far from arbitrariness as the latter: less precise, debatable, with risks in the choice that the scientific community diminishes by distributing the danger among its members, until time shows with its results the rightness of the bet.

Kuhn's emphasis that the scientific community is inseparable from the theoretical and empirical elements of the paradigm-disciplinary matrix clearly differentiates his conception of science from the traditional ones. He will go so far as to say—in

a “circular, but not vicious” way—that a paradigm is what a scientific community shares, while a scientific community is one that shares a paradigm. There are several reasons for him to introduce this notion. On the one hand, the historian of science visualizes the changes in theories (paradigm-disciplinary matrixes) as a change in the beliefs of the only ones with the authority to decide them, the community of experts, in a context in which it was shown that there were no crucial facts that forced the discarding of one theory (paradigm-disciplinary matrix) and the adoption of another, nor a completely common language to guide the discussion. On the other hand, the existence of normal science means that the development of the paradigm-disciplinary matrix is not due to any isolated scientist but to the joint effort of a group of researchers that makes it advance when they solve under its guidance the innumerable problems it poses.

In addition, Kuhn proposes to abandon the *teleological notion of progress toward truth*, according to which changes in the paradigm-disciplinary matrix bring scientists ever closer to the truth, preferring instead to speak of a development—analogue to that proposed by the theory of evolution with respect to species—that can be defined *from* its previous stages, as opposed to a process of evolution *toward* something.

Kuhn's Relations With Classical Philosophy of Science

As regards his relations with classical philosophy of science, Kuhn—who expected to find in Popperians his best allies—tries to show how his ideas follow those of Karl Popper's, although in his own way.

The vehement rejection he suffered taught him that, although they coincided in some aspects, the Popperian community and Popper himself would not forgive him for the pragmatic, especially psychological and sociological, aspects of his proposal. From then on, he would be read as somebody who ascribes an irrational behavior to scientists instead of admitting the necessity (shown by his analyses) of modifying the concept of scientific rationality subscribed to until then.

The situation is equally paradoxical in relation to logical empiricism, which is supposed to be the adversary defeated by his work.

Apart from the stereotypes that turned it into the *straw man* everybody uses to revile it, this current in the philosophy of science presents a wide range of aspects and orientations which even justify the enthusiastic recommendation of Kuhn's SSR that Carnap wrote in his own hand on the back of the official letter of acceptance which he sent to Charles Morris.

There are clear affinities between Kuhn's proposal and that made by the logical empiricists Neurath and Zilsel, who carry out more *historical* and *sociological* analyses than the more *formalist* one represented by Carnap's work.

And there are affinities even with the latter, although Carnap did not consider the historical and social empirical studies of science as belonging to the philosophy of science, understood as the *logic* of science, but to the more inclusive category *theory* of science. Examples of such affinities include Carnap's acceptance of (1) the noncumulative conception of scientific development (positing a sort of incommensurability between different linguistic or conceptual frameworks), (2) the role of pragmatic considerations in the scientists' decision of using a linguistic framework, and (3) accepting or rejecting particular hypotheses (the latter also stressed by Neurath, Frank and Hempel's late work).

The fact that the *Postscript* to SSR written by Kuhn in 1969 was the last work published in the most ambitious publishing project coming from logical empiricism, the (*International*) *Encyclopedia of Unified Science*, constituted the perfect ending for an era, not because Kuhn finished with that tendency forever but because with him some interests that had begun in Vienna at the beginning of the century would find their way forward.

Further Developments

After the clarifying articles written in 1969, in which he replaces the term *paradigm* with the terms *disciplinary matrix* and *shared example* (or *exemplar*), Kuhn also stopped writing about disciplinary matrixes and instead wrote about *theories*. This doesn't mean, however, that Kuhn abandoned the *concept* of paradigm, in either of the two basic senses—the *original* sense of exemplar and the more overarching one of disciplinary matrix—but only the term.

Notwithstanding, that he uses the term *theory* doesn't mean that he accepted the classical concept of theory. According to his own explication of the concept of theory, it consists, among other things, of *symbolic generalizations*, in its (more) *theoretical* or *formal* part, *together with* examples of their function in use (*exemplars* or *paradigms* in the *original* sense), in its (more) *empirical* or *applicative* part. As for the link between the two parts, it is established by what Kuhn calls "special (or appropriate) versions" or "particular (or detailed) symbolic forms (or versions or expressions)," which acquire the symbolic generalizations in order to be applied to particular problems (situations, phenomena). And although Kuhn does not elaborate in detail what the relationship between symbolic generalizations and their particular forms is, he makes it very clear that this is not one of logical deduction.

Some historians and philosophers of biology have found the notion of *exemplar* fruitful for their analyses, either by holding that theories in the biological (and/or biomedical) sciences possess a particular structure distinct from that of physical theories as Darden (1991) and Schffner (1986) argue. or by considering that this is not the case, if analyzed within the framework of some version of the semantic conception of theories. Lorenzano (2007) and Schaffner (1993) provide such analyses.

In fact, Kuhn's concept of theory, which reformulates that of paradigm as a disciplinary matrix and contains the *original* sense of the former, finds an even more satisfactory explication in the framework of the semantic conception of theories, especially in that of the structuralist view, as Kuhn himself early recognized and continued to do so until the end of his days.

In the structuralist version of the semantic conception of theories that acknowledges the presence of irreducibly pragmatic and historically relative elements in the analysis of scientific theories as we see in Balzer et al. (1987), the Kuhnian notion of symbolic generalization is made more precise by means of the notion of *fundamental law/guiding principle*, that of exemplar through that of *paradigmatic application* and the relation between symbolic generalizations and the specific forms they adopt with the relation of *specialization*.

Whereas the overall synchronic structure of a theory is thus given by a *hierarchical (non-deductive) structure organized by the relation of specialization*

and the scientific development during the period of normal science is represented in it by the notion of *theory-evolution*.

And together with the (*usually partial*) *incommensurability* existing between theories separated by a scientific revolution, the structuralist view of theories also makes possible the representation of other inter-theoretical changes susceptible to be found in the history of science, such as the *emergence* of theories and the *reduction* between them.

PARADOXES

Typically when we reason, we start from premises that we believe, proceed through inferences based on principles of logic that we could not doubt, and arrive to a conclusion that we accept. *Paradox* is the name we give to situations in which this *doesn't* happen. Paradoxes arise when an argument seems to show that something has gone awry in our reasoning, when the argument itself seems airtight and yet the conclusion seems absurd. This is different from making a mistake on one's math homework where an error in a calculation might lead one to mistakenly deduce $0 = 1$. But the difference is mainly one of degree; while it is usually straightforward to spot a dropped minus sign or division by 0 in math homework mistakes, paradoxes are not so easily resolved. Indeed, resolution of a paradox usually requires giving up a firmly held premise, adopting unfamiliar methods of reasoning, or accepting an intolerable conclusion. For this reason, the study of paradoxes has been

behind major upheavals of thought and scientific innovations, as the resolution of paradoxes required either new ways of reasoning or substantial revisions of commonly held beliefs.

This entry aims to explain what paradoxes are and the ways that they have been characterized and solved over the course of the history of philosophy. We will begin by describing some examples in detail, illustrating the ways that paradoxes can arise in considerations of infinity, vagueness, and self-reference. These examples will then serve as the raw materials for a subsequent discussion on the ways that paradoxes have been analyzed and understood. The study of paradoxes has been a major concern within philosophy for millennia, so the list of examples considered here and the discussion about them will inevitably be incomplete—we do not discuss, for example, moral paradoxes or paradoxes of rational action—but our aim will be to highlight the shared features of the paradoxes and the ways that people have tried to solve them. With these features in view, we will conclude with a discussion about *why* the resolution of paradoxes has, for various corners of philosophy and science, been an urgent priority and how these solutions have undergirded important conceptual advances in the relevant fields.

Examples of Paradoxes

Zeno's Paradox

Zeno's paradox is really a family of paradoxes that derive contradictory conclusions from the infinite divisibility of time and space. These paradoxes, originally due to Zeno the Greek in the 5th century B.C.E., have survived to the present day by being passed down secondhand through the work of other philosophers, principal among them being Aristotle. For the sake of brevity, we will focus on two versions of Zeno's paradox, which stem, in particular, from the fact that a finite interval of time can be broken up into an infinity of subintervals of positive length.

The first concerns motion from point A to point B. Suppose you begin a journey from point A to point B, which are at some positive distance apart from one another. Before you arrive to point B, you must arrive at the midpoint C_1 along the

path from A to B. Then, continuing along the path, before you reach B, you must also reach the midpoint C_2 along the path from C_1 to B. And this continues: Once you reach the point C_n , you must first reach the midpoint C_{n+1} along the path from C_n to B, for $n = 1, 2, 3, \dots$. Therefore, you have to perform infinitely many arrivals before you can arrive to point B. Infinitely many actions cannot be performed in finitely much time. Therefore, it is impossible to travel from point A to point B. Notice, moreover, that, in this argument, point A and point B were completely arbitrary locations at some distance apart, so this argument seems to show that going from anywhere to anywhere else leads to contradiction or, in other words, that motion is impossible.

A more vivid variant of this paradox is formulated in terms of a race between Achilles and the tortoise. Achilles is an athletic fellow and a swift runner, while the tortoise ambles about at a glacial pace. It should be clear that, even if the tortoise gets a head start, Achilles will at some point overtake the tortoise. Yet before Achilles overtakes the tortoise, he must advance to a location at which the distance between him and the tortoise has been halved. And then before he overtakes the tortoise, he must next reach a location at which *that* distance between him and the tortoise has been halved, and so on. Thus, it appears that Achilles, no matter how quickly he sprints, can never catch up to the tortoise.

Sorites Paradox

A second paradox, also of ancient origin, is called the *Sorites paradox*. This paradox concerns vagueness. One version of the argument runs as follows. If one removes a single grain of sand from a heap of sand, it is still a heap of sand. A single grain of sand, by itself, is certainly not a heap of sand. Now suppose we are given a heap of sand. It will contain some finite number of grains of sand. For concreteness, let's assume it consists of 14,379 grains of sand. Now suppose that, one by one, we remove the grains of sand from the heap. We perform the operation of removing a single grain 14,378 times, until we arrive at a single grain of sand left. So we arrive at something which is certainly not a heap of sand, but we started with a heap and, since the removal of a single grain

cannot turn a heap into a nonheap, it must be the case that the single grain of sand is a heap as well. This is a contradiction.

A similar puzzle, recorded by the ancient Greek historian and biographer Plutarch, concerns the fabled ship of Theseus, the fabled founder-king of Athens. Ships have parts that rot, break, and need to be replaced. After several years of constant sailing, Theseus's ship had undergone so much maintenance that literally every part been replaced and none of the physical parts of the original ship remained. Is the ship that resulted after years of sailing the same as the ship with which Theseus began? The fact that every piece of the latter ship differs from the former one seems to mean that it is a *completely different ship*. But one would not say that one has a new boat just because a part gets replaced or a plank gets mended. If the ship is different, then there must be some modification where the transformation took place, but none can be located in the ship's entire history of repair.

The Sorites paradox and related puzzles deal with vague concepts, whose characteristic feature is that they have borderline cases, where competent speakers do not know how to respond to a question about whether or not a concept applies. A single grain is not a heap, a story-high pile of sand certainly is, but somewhere in the middle, individuals will not necessarily know how to respond to the question of whether or not a certain quantity of sand constitutes a heap. The concepts considered in the Sorites paradox, moreover, satisfy a *principle of tolerance* whereby small changes to an object do not change whether or not the concept applies.

The Liar Paradox

The Liar paradox comes from trying to determine the truth or falsity of a sentence that says of itself that it is false. One of the earliest appearances of this sort of puzzle is in the Bible, where Paul of Tarsus relates an anecdote of a Cretan man who says that all Cretans are liars. This, by itself, is not so difficult to interpret in a way that dissolves the sense of paradox—perhaps this Cretan meant that all *other* Cretans are liars, or that all Cretans utter falsehoods some, but not necessarily all, of the time. Even under the simplifying assumption that the Cretan intended to suggest that every single

Cretan, including himself, utter falsehoods all the time, there is not yet a paradox. The sentence, to be sure, cannot be uttered truthfully. For if the sentence is true, then the Cretan must be lying, which means it must be false. But if the sentence is false, that just means that the speaker is a liar and there is some Cretan who is truth-telling, which is not a paradoxical conclusion.

But suppose instead of saying that all Cretans are liars, Paul's Cretan said it of himself or, more transparently, had simply said "this sentence is false" or had introduced a sentence *L* which said "*L* is false." In this case, it seems impossible to ascribe either truth or falsity to the sentence *L*. If *L* is true, then what it says must be the case, so it is false. If *L* is false, then it must not be the case that what it says is the case, so it is not false. Additionally, it seems to be no help to this paradoxical conclusion to allow for sentences to be neither true nor false. The sentence *L* can be modified to form the following sentence *L'*: "*L'* is either false or neither true nor false." There are three possibilities: *L'* is true, *L'* is false, or *L'* is neither true nor false. The first two possibilities lead to contradiction in exactly the same way that *L* did. But additionally, in the case that *L'* is neither true nor false, then what it says of itself is true, so it is true, hence can *not* be said to be neither true nor false. This leads once more to contradiction.

Russell's Paradox

Russell's paradox, introduced by the British philosopher and logician Bertrand Russell, is a paradox that concerns sets. Naively, a *set* is just a well-defined collection of objects. One way of describing a set is just to list its elements. For example, there's a set {1, 2, 3} which consists exactly of the elements 1, 2, and 3. But another way to describe a set is to give the conditions for membership in the set. For example, the set of physical objects that weigh less than a kilogram; it isn't possible to simply list all such objects, but there is a criterion for membership. To check whether some physical object is in the set or not, one can simply put it on a scale. In the context of mathematics, such ways of introducing sets—such as the set of prime numbers, the set of points on a given line, the set of deducible theorems from a given set of axioms—are completely ubiquitous.

Russell's paradox begins by considering the property of non-self-membership and considering the set of all sets with this property. Some sets are members of themselves and some are not. The set of all sets, assuming it exists, is a set, so it is a member of itself, while the empty set is a set with no members, so it is not a member of itself. So now consider the set *R* consisting exactly of those sets which are not members of themselves. We know already that the set of all sets is not in *R* and the empty set is in *R*. But is *R* a member of itself?

Herein lies the paradox: if *R* is a member of itself, then, by definition, it must have the property of non-self-membership and that means that *R* is not a member of itself. Therefore, *R* can't be a member of itself. But if *R* is *not* a member of itself, then it has the property of non-self-membership and consequently *R* must be a member of the set of all sets with the property of non-self-membership, which is to say *R* must be a member of *R*. We see, then, that if *R* is a member of itself, then it isn't, and if it isn't, then it is. This is a paradox.

Variations on Russell's paradox exist in natural language as well. For example, the well-known logic textbook *Model Theory* by the model theorists C. C. Chang and Jerome Keisler (2013) contains the following dedication: "For the amusement of all those who gave us help, we dedicate our book to all model theorists who have never dedicated a book to themselves" (p. xiv).

Did they dedicate the book to themselves? As in Russell's paradox, either way of answering this question seems to lead to contradiction. Another version was introduced by Kurt Grelling, who defined the adjective *heterological* to describe those adjectives that do not describe themselves. So, "monosyllabic" is heterological (because "monosyllabic" is not monosyllabic) but "polysyllabic" is not. Grelling's paradox arrives at the self-contradictory conclusion that *heterological* must be both heterological and not heterological.

Problems and Solutions

Willard van Orman Quine introduced a helpful way of distinguishing the varieties of paradoxes. If a paradox is a kind of argument that establishes an absurd conclusion, we can call this conclusion the *proposition* of the paradox. For example, the proposition of Zeno's paradox of Achilles and the

Tortoise is the proposition that Achilles never overtakes the tortoise. In other examples, the proposition of a paradox is somewhat less clear. For instance, Quine says of Grelling's paradox that its proposition is a self-contradictory compound proposition to the effect that our adjective is and is not true of itself. He then defines the *veridical* paradoxes to be the ones where the proposition is true, and the *falsidical* paradoxes to be the ones where the proposition is false, there being a fallacy at some place in the argument. Motion *is* possible, Achilles *does* in fact overtake the tortoise and fallacies can be found in each of the arguments. As a consequence, Zeno's paradoxes are falsidical. On the other hand, a well-known theorem of Stefan Banach and Alfred Tarski establishes the unit ball; that is, the area inside the sphere of radius 1 can be partitioned into finitely many pieces, moved around by rotations and translations in three-dimensional space, and thus rearranged to form two balls of the same volume as the first. This mathematical result is known as the *Banach–Tarski paradox*. The conclusion, despite flying in the face of our spatial intuition, is nonetheless a mathematical fact. This paradox, then, is veridical.

Quine's distinction classifies paradoxes *retrospectively*, from a point of view reached after the paradox has been solved. The veridical paradoxes are the ones where we resolve them by learning somehow to accept the intolerable conclusion. In the case of the Banach–Tarski paradox, for example, the absurdity of the conclusion is mellowed once one learns that the pieces of the partition are not obtained constructably and cannot be assigned volume—the components of the partition bear no resemblance to the kinds of pieces that could be physically realized by a decomposition of a ball in the world. The falsidical paradoxes are the ones we resolve by finding a fallacy in the argument that blocks the inference to the paradox's proposition. In the case of Achilles and the Tortoise, we noted that it doesn't follow that a duration of time which can be broken up into infinitely many periods of positive duration must therefore be infinite. Therefore, the inference that Achilles cannot reach the tortoise was based on bad reasoning and, once we give up this step in the argument, the paradox dissolves. But the paradoxes that are not yet resolved, for Quine, belong to a third category, the *antinomies*.

But how can a paradox be solved? One of the steps in Zeno's paradox, for example, was inferring from the fact that infinitely many tasks are performed, that infinitely much time must have passed. But this doesn't follow. If Task 1 takes $t/2$ many seconds, and Task 2 takes $t/4$ many seconds, and Task 3 takes $t/8$ many seconds, and so forth, then the amount of time taken up by performing Task n for all $n = 1, 2, \dots$ can be expressed by

$$\sum_{n=1}^{\infty} \left(\frac{t}{2}\right)^n = 1$$

using the sum-formula for a geometric series. So doing all the infinitely many tasks takes only t many seconds, which is a finite duration of time. This basic calculus fact intervenes to show us that the inference involved in Zeno's paradox was incorrect, and the paradox dissolves.

The solution of the Sorites paradox is considerably less straightforward. For this paradox, there is no consensus on even what constitutes the *source* of the paradox. In the paradox of the heap, it is fairly uncontroversial that a single grain does not constitute a heap, so treatments of the paradox tend to focus on the principal of tolerance being a heap is supposed to satisfy—namely, that a heap minus a single grain is still a heap. Some commentators believe that the concepts we employ when talking about heaps or other vague notions are indeterminate or incomplete. This requires, then, that some heap minus a single grain of sand becomes *indeterminate*. In order to avoid simply reproducing the paradox, then, these theories have to account for *higher order vagueness*, arguing that the concept of *determinate heap* is vague in the same way as *heap* is. Other theories argue that there, in fact, is a sharp boundary separating the heaps from the nonheaps, and the phenomenon of vagueness can be understood as a consequence of our *ignorance* of that boundary. On either account, the principle of tolerance associated to vague concepts is rejected or tweaked to block the inference that leads to contradiction in the Sorites paradox.

Why Paradoxes Matter for Science

Paradoxes, on first blush, appear to be more like riddles or sources of amusement rather than the objects of serious scientific inquiry. For example,

the Sorites paradox largely concerns concepts that occur in natural language, like “a heap of sand,” rather than more precisely quantifiable notions that appear in empirical science, like “greater than 50 grams of sand.” When vagueness would present a problem for the development of a scientific theory, reference to vague notions can often be replaced by vocabulary to which soritical difficulties do not apply. However, the notions of *truth* and *set*, called into question by the Liar paradox and Russell's paradox respectively, play a fundamental role in logic and the foundations of mathematics and cannot be so easily replaced or dispensed with. The urgency of dealing with these fundamental paradoxes in formal theories of mathematics, logic, and language has motivated several major conceptual advances in each of these realms.

Russell's paradox was discovered by Bertrand Russell, who came across the paradox while trying to make sense of Gottlob Frege's work in the logicist program of reducing mathematics to logic. Frege had worked out an elaborate formal development of mathematics based on logical principles, but one of the axioms of his system was his Basic Law V, which roughly asserts, in contemporary language, that, for every property, there is a set consisting exactly of the objects that possess that property. For example, the property of being a prime number can be used to form the set of prime numbers by application of this principle. Russell observed that paradox results by applying this principal to the property of non-self-membership as described above. Upon learning of the paradox, Frege felt that a contradiction had been discovered at the heart of mathematics itself: His reply to Russell (quoted in Quine 1966) said “arithmetic totters.”

In order to avoid this paradox, Russell and Alfred North Whitehead, in their *Principia Mathematica*, introduced a theory of *types*. In simplified form, the objects of Type 0 are the individuals, objects of Type 1 are collections of individuals, objects of Type 2 are collections of collections of individuals (or, equivalently, collections of objects of Type 1), and so on. In this system, an object of Type n could only be an element of an object of Type $n + 1$, which means that no object could ever be an element of itself. In this way, the paradox was blocked, although at the cost of working

with a cumbersome formalism. Later approaches to the foundations of mathematics, by way of Zermelo-Frankel set theory, eschew the theory of types but prohibit sets being members of themselves. In particular, in these systems, there can be no set of all sets. Finding a system that could serve as the foundations of mathematics was a central research program within 20th-century mathematics, and Russell's paradox was a central consideration in the way the formalism eventually took shape.

The Liar paradox, likewise, has had a substantial influence on the way truth has been understood within logic and mathematics. Avoiding antinomies like the liar motivated Alfred Tarski to introduce a definition of truth in formal languages, which has since become a fundamental notion in model theory and plays an important role in linguistics in the area of formal semantics. A key feature of Tarski's approach was that truth for expressions in a language L being analyzed, called the *object* language, while the definition itself was expressed in a different, possibly richer language called the *metalinguage*. In this approach, expressions about the truth of sentences in L cannot be expressed in L itself, so the liar sentence cannot be formulated. Indeed, by making use of a formalized version of the Liar paradox, Tarski showed that no sufficiently rich formal language can contain its own truth predicate; he showed that, within the object language, it is not possible to define the set of true sentences in that language. An alternative approach, in which the object language may contain its own truth predicate but truth and falsity are only applied to *some* of the sentences, was pursued by Saul A. Kripke and the resulting theory was very influential for both philosophy and mathematical logic.

The aforementioned advances were motivated by a desire to create formal systems that could capture the features of truth and our reasoning about sets while eliminating the paradoxes, but one further application—perhaps the most striking of all of them—involved finding the liar paradox where it was not expected. Gödel's incompleteness theorem, originated by Kurt Gödel, addresses the question of whether one could discover all of the truths of arithmetic. For example, children learn in school that “for every

number n and every number m , $n + m = m + n$ ” and, perhaps later, learn how to apply the principle of induction to prove formulas like

$$1 + 2 + \dots + n = n(n + 1)/2$$

which holds for all natural numbers n . Clearly, there are infinitely many such truths, but it is natural to ask if there are finitely many principles from which all such truths could be deduced or, perhaps, if one could program a computer to begin churning out a list of truths about the natural numbers so that, given infinitely much time, every truth would eventually appear. In contemporary language, Gödel showed how any collection of arithmetic truths that could be described by a computer program must be incomplete. And he did this by showing how, from such a set of truths, one could produce a statement that said of itself “I am not provable from this set of statements.” This is exactly analogous to the liar sentence, except with provability from the axioms taking the role of truth. If Gödel's statement were provable, then, assuming the set of statements were consistent, it would be true, hence not provable. This shows this sentence is *not* provable and thus that the set of provable statements must be incomplete. In other words, there must be some arithmetical truths that elude our grasp, even given arbitrary computational strength and time. In this way, Russell's paradox and the Liar paradox have underlain some of the most significant developments in philosophy, logic, and mathematics.

PERTURBATION THEORY

This entry aims to explain essential elements of perturbation theory and their conceptual underpinnings. It is not meant as a summary of popular perturbation methods, though some illustrative examples are given to underline the main methodological insights and concerns. We also give brief explications of the mathematical notions of *limit*, *continuity*, *differentiability*, *convergence*, and *divergence*, which provide the necessary foundation.

The role of perturbation theory is to study the effects of small disturbances (or perturbations) on the behavior of a (possibly only hypothetical) system irrespective of the source of the disturbance. For instance, the disturbance may have its physical origin in the environment of a system, as when a system receives small amounts of energy from the outside or when an experimental setup is slightly disturbed by the vibration caused by a

truck on a nearby street. The disturbance may have been added to the modeling equations by design in order to simplify the study of a system, as is the case when we neglect small quantities to obtain more mathematically tractable equations. The disturbance may even be due to experimental error and uncertainty or to computational error.

The effects of small disturbances are sometimes small too, in which case they are usually called *regular* perturbations. As James G. Simmonds and James E. Mann (1998) explain, regular perturbations “are assumed nearly every time we construct a mathematical model of a real world phenomenon. Our choice of language reflects this: the flow is *almost* steady, the density varies *essentially* with altitude only, the conductivity is *virtually* independent of temperature, the spring is *nearly* linear, the friction is *practically* negligible” (p. 1). However, mother nature isn’t always that cooperative and sometimes the effect of small disturbances is very large indeed; in such cases, we talk of *singular* perturbations. We will return to the distinction between regular and singular perturbations later. Perturbation theory is central to the scientific method in two important but distinct respects. On the one hand, good applied mathematical practice demands that one considers possible disturbances before assessing whether a mathematical model correctly captures the behavior of a system. Thus, even “exact” mathematical theories and models enter the realm of perturbation theory as soon as they are applied. On the other hand, while it is typical of introductory courses on “mathematical X”—for example, mathematical physics, biology, economics—to focus exclusively on problems that can be solved exactly, this desirable event of complete tractability only rarely happens in applied mathematical practice, either because we don’t know exactly solvable models or because the accurate models turn out to be theoretically impossible to solve exactly. Hence instead of using “demonstrative solution methods” one necessarily relies on methods that extract approximate solutions. In this case, a problem is said to be “solved” in the sense that we can get approximations that are close enough, even if we can never actually solve it exactly (we return to this below).

One of the beautiful and powerful aspects of perturbation theory is that it addresses the two concerns with the very same set of mathematical methods. These methods, to be sure, differ from

other mathematical methods that are central to science. For instance, deductive or axiomatic approaches focus on whether axioms are true and on whether certain statements are logical consequences of sets of axioms. Probability theory concentrates on quantifying how probable it is that a statement will be true. However, the few remarks above suggest that in most concrete contexts, it is not enough to ask what is true, what logically follows from what, and what is probable; we also need to ask: *If things were changed or disturbed a little, what would the effect be?* This is precisely the role of perturbation theory and what distinguishes it from other mathematical disciplines.

Mathematical Background

To understand the main concepts and methods of perturbation theory, we introduce a few essential mathematical ideas. We believe that they will be accessible to most readers who have an intuitive grasp of the concept of derivative and, to a lesser extent, of the concept of integral.

We begin with the crucial notion of *limit* and the related notion of *convergence*. Intuitively, a limit is the mathematical object (often, a number or a function) that is approached by an infinite sequence. Consider a classical example. Even if we know by definition that π is the ratio of the circumference of a circle to its diameter, it is impossible to write down its value as a number in conventional format since its decimal expansion is infinite and nonrepeating. However, around 250 BCE, Archimedes made the first known use of sequences to calculate the value of π to arbitrary precision, at least in principle.

As we see in Figure 1, the perimeter of the hexagon circumscribed in the unit circle is equal

Figure 1 The First Three Items in Archimedes' Sequence of Polygons Circumscribed in the Unit Circle to Approximate π

to 6, since it can be decomposed in six equal equilateral triangles of Side 1. Archimedes' brilliant idea was that, if we know the side s of a polygon circumscribed in a circle, we can find the side s' of a polygon with twice the number of sides by elementary trigonometry (see Figure 2):

$$s' = \sqrt{\left(1 - \sqrt{1 - \left(\frac{s}{2}\right)^2}\right)^2 + \left(\frac{s}{2}\right)^2} \quad (1)$$

Figure 2 The Trigonometric Relation Exploited by Archimedes

Using this formula, we can successively find the length of the sides of circumscribed polygons with 6, 12, 24, 48, . . . sides, from which it is easy to find approximations of the ratio of the perimeter to the diameter. This gives us the following sequence of approximations:

$$\begin{aligned} p_1 &= 3.0000 & p_2 &= 3.1058 & p_3 &= 3.1326 & p_4 &= 3.1394 \\ p_5 &= 3.1410 & p_6 &= 3.1415 & p_7 &= 3.1416 & & \dots \end{aligned}$$

Here, we round to the fourth decimal place for convenience. The bigger k is, the closer p_k will be to π . In that sense, we say that the sequence of p_k converges to π as k goes to infinity (denoted $k \rightarrow \infty$). Alternatively, we say that π is the limit of this sequence as $k \rightarrow \infty$.

Limits of sequences are also essential to the manipulation and interpretation of *infinite series*:

$$S = \sum_{k=0}^{\infty} a_k = a_0 + a_1 + a_2 + \cdots + a_n + \cdots \quad (2)$$

Consider the perfectly well-defined finite sum

$$S_N = \sum_{k=0}^N a_k = a_0 + a_1 + a_2 + \cdots + a_N \quad (3)$$

of $N + 1$ terms. The sums $S_1, S_2, S_3, \dots$ form a sequence. The sum S of an infinite series is interpreted as the limit of this sequence, that is, the number or function that is approached as the number $N + 1$ of terms summed approaches infinity. In mathematical notation, we write

$$S = \lim_{N \rightarrow \infty} S_N = \lim_{N \rightarrow \infty} \sum_{k=0}^N a_k = \sum_{k=0}^{\infty} a_k. \quad (4)$$

If no such finite S exists, the series is said to *diverge*. However, if the series has a limit S , then it is possible to use a finite number N of terms to approximate the value of S . Since this practice involves retaining the first N terms of the series and discarding the rest, this is called a *truncated series approximation*.

There is a substantive arsenal of tests available to determine whether series converge. But what is the status of series that don't converge to any number or function? In the 19th century, Niels Henrik Abel provocatively put it as follows:

The divergent series are the invention of the devil, and it is a shame to base on them any demonstration whatsoever. By using them, one may draw any conclusion he pleases and that is why these series have produced so many fallacies and paradoxes [...]. (cited in Hoffman, 1998, p. 218)

From the point of view of analysis, they are said to have no meaning since they don't refer to anything; alternatively, the series is said not to be valid.

However, as we will see, there are important differences between this perspective and that which provides the conceptual foundations for perturbation theory. Indeed, additional subtleties come into play when we consider *series of functions* that may (or may not) converge to a function, and many of the most successful applications of mathematics in science have only become possible by an improved understanding of how divergent series can be used to obtain reliable results.

First, we observe that functions themselves may have a limit near a point; this is an application of the same idea we've introduced above. Consider a function $f(x)$ defined on an interval (or more generally, on an open set) A , and suppose we wish to know what value the function $f(x)$ approaches as

the argument x becomes increasingly closer to a point a within the interval. We can think of a sequence of arguments $a_0, a_1, a_2, a_3, \dots$ and of the corresponding sequence of values $f_1 = f(a_1), f_2 = f(a_2), f_3 = f(a_3), \dots$. If the sequence of k s approaches a given finite value L as the k s approach a , for any choice of sequence of k s that approach a , then we say that L is the limit of the function $f(x)$ as x approaches a . In rigorous mathematical notation, we say that a function $f(x)$ has the limit L as $x \rightarrow a$ if

$$(\forall \epsilon > 0)(\exists \delta > 0)(x \in A \ \& \ |x - a| < \delta \Rightarrow |f(x) - L| < \epsilon). \quad (5)$$

A function $f(x)$ is said to be *continuous* at the point $x = a$ provided that

$$\lim_{x \rightarrow a} f(x) = f(a). \quad (6)$$

It is continuous on an interval (or open set) A if it is continuous at all points a in the interval. This definition captures the intuitive idea that a function is continuous if its graph is an unbroken curve, without holes or jumps.

The treatment of limits at ∞ is nearly the same, because the ideas are very similar (some would say identical except in form). We say that

$$\lim_{x \rightarrow \infty} f(x) = L \quad (7)$$

if

$$(\forall \epsilon > 0)(\exists X)(x > X \Rightarrow |f(x) - L| < \epsilon). \quad (8)$$

Here, the large X plays the same role as the small δ earlier.

This is known as the *epsilon-delta* definition of limit and it is due to the efforts of Cauchy, Bolzano, and Weierstrass to provide rigorous foundations for calculus in the early 19th century. This definitional approach provides concrete meanings for more intuitive phrases, used since the time of Newton, such as “we can make the error $|f(x) - L|$ as small as we please by taking x sufficiently close to a ,” without appealing to infinities and infinitesimals.

Following Carathéodory, we say that f is *differentiable* at $x = a$ if there exists a function $\phi(x)$ that is continuous at $x = a$ such that

$$f(x) = f(a) + (x - a)\phi(x), \quad (9)$$

in which case $f'(a) = \lim_{x \rightarrow a} f(x) = f(a)$. This is of course the equation of the tangent of the function f at the point $x = a$. The process can be repeated to find the derivative of the derivative (known as *the second derivative*) $f''(x)$, the third derivative $f'''(x)$, and so on. This gives rise to an *expansion* of the function f about the point a . When a function has $N + 1$ derivatives in a neighborhood of $x = a$, then there exists a continuous function $\phi_{N+1}(x)$ such that

$$= \sum_{k=0}^N \frac{1}{k!} f^{(k)}(a)(x-a)^k + \phi_{N+1}(x)(x-a)^{N+1}. \quad (10)$$

This is known as *Taylor's theorem*, and the resulting Taylor series are among the most useful in applied mathematics.

To simplify expressions such as the one in Equation 10, we can use the “big-Oh” notation, first used by Bachmann and popularized by Landau. To indicate that $f(x)$ and $g(x)$ are of similar size near $x = a$, we say that f is order g (denoted $f(x) = O(g(x))$ near a). More precisely, we say that

$$f(x) = O(g(x)) \quad \text{near } x = a \quad (11)$$

if there exists a constant K such that for all x sufficiently near a we have

$$|f(x)| \leq K|g(x)|. \quad (12)$$

In theory K may be very large—indeed arbitrarily large or arbitrarily small. But in practice, when the use of a perturbation method is successful, K is usually of quite moderate size. With this notation, Equation 10 simply becomes

$$f(x) = \sum_{k=0}^N \frac{1}{k!} f^{(k)}(a)(x-a)^k + O((x-a)^{N+1}). \quad (13)$$

Following the same idea, but generalizing it, perturbation theory uses truncated series of functions:

$$S_N(\varepsilon) = \sum_{n=0}^N a_n \varphi_n(\varepsilon). \quad (14)$$

The sequence $\varphi_0(\varepsilon), \varphi_1(\varepsilon), \dots, \varphi_N(\varepsilon), \varphi_{N+1}(\varepsilon), \dots$ may be infinite; these functions are often called *gauge functions*. The most usual gauge functions are simple powers of $1, \varepsilon, \varepsilon^2, \dots$ (i.e., ...) when we are interested by the behavior of the function as $\varepsilon \rightarrow 0$, or powers of $(\varepsilon - a)$ when we are interested

in the behavior of the function as $\varepsilon \rightarrow a$. Notice that when ε is near 0 or a , as the case may be, the higher the power N of ε^N or $(\varepsilon - a)^N$ is, the closer it will be to 0; in other words, for gauge functions, each function in the sequence is smaller than the previous one near the limit point:

$$\lim_{\varepsilon > 0} \frac{\varphi_{n+1}(\varepsilon)}{\varphi_n(\varepsilon)} = 0 \quad (15)$$

This is only useful if the φ_k are somehow simpler than the original function f . Indeed we know an example,

$$\ln z = \sum_{k=1}^N W^{(k)}(z) + O(W^{(N+1)}(z)) \text{ as } z \rightarrow 0 \quad (16)$$

of an asymptotic expansion of a simple function in terms of iterates of a less well-known function, the Lambert W function, but if this is useful at all the example would be a startling exception (see Corless et al., 1996). The normal case has each φ_k simpler than the original f .

One might also say that perturbation methods are an application of the theory of truncated *formal* series. If one does not explicitly truncate the series as in Equation 14 but writes $a_0\varphi_0(\varepsilon) + a_1\varphi_1(\varepsilon) + a_2\varphi_2(\varepsilon) + \dots$, one describes the series as “formal.” This means that issues of convergence as $N \rightarrow \infty$ are usually irrelevant, and in practice, divergent series are often used. The point is, and it is a simple one although there is a great deal of confusion in the literature, that there are two limits of interests with series:

$$\lim_{N \rightarrow \infty} S_N(\varepsilon), \text{ where here } \varepsilon \text{ is fixed, and } \varepsilon \neq 0,$$

encountered first in most calculus classes, whence issues of convergence of a sum of an infinite number of terms arise, and the other

$$\lim_{\varepsilon \rightarrow 0} S_N(\varepsilon), \text{ where here } N \text{ is fixed,}$$

the relevant limit for perturbation series. In the quite common case that the second limit as $\varepsilon \rightarrow 0$ exists and is finite but the first does not (the series diverges as $N \rightarrow \infty$) the series is said to be “asymptotic.” The cure for divergence as $N \rightarrow \infty$ is simply

to keep N fixed. The other limit, as $\varepsilon \rightarrow 0$, often provides all the accuracy one needs.

This point of view allows one to use a fixed number of terms (*any* fixed number of terms) of a series that would diverge if we were so foolish as to let $N \rightarrow \infty$. Using gauge functions, that is, functions that are smaller than the previous in a neighborhood of the limit point, we find that perturbation series for $f(a + \varepsilon)$ is

$$f(a + \varepsilon) = \sum_{k=0}^N p_k \varphi_k(\varepsilon) + O(\varphi_{N+1}(\varepsilon)) \quad (17)$$

if

$$\lim_{\varepsilon \rightarrow 0} \frac{|f(a + \varepsilon) - \sum_{k=0}^m p_k \varphi_k(\varepsilon)|}{|\varphi_{m+1}(\varepsilon)|} \quad (18)$$

is bounded (*mutatis mutandis* as $t \rightarrow \infty$), for each $m = 0, 1, 2, \dots, N$. Notice that N is fixed and does not go to infinity.

The Use of Series in Perturbation Theory

With the mathematical concepts introduced in the previous section, we are now ready to examine how perturbation methods work. When facing a hard problem, one can use the following conceptually (and with some practice, mathematically) simple three-step method. The *first step* consists in introducing a small positive parameter ε , known as a *perturbation parameter*, in the hard problem that you may not know how to solve or that can be provably unsolvable by explicit methods. So, instead of having only one hard problem, we are now in the presence of an infinite collection of hard problems, one for each value of ε . This may not look like progress, but that is only the first step. The idea of introducing a perturbation ε is sometimes an obvious thing to do (e.g., when a value of ε such as 0 really simplifies things), and sometimes it is not obvious at all. Very clever choices are sometimes needed, and knowing what choice to make is in many respects an art rather than a science. However, in scientific use, the modeling context may sometimes dictate where to introduce the ε as it will correspond to a quantity that is small, such as air resistance, friction, and so on. For the *second step*, assume that the answer is a function of ε and assume that

the answer is in the form of a truncated power series in ε :

$$ANS(\varepsilon) = \sum_{n=0}^N \alpha_n \varepsilon^n \quad (19)$$

More generally, we could use any collection of gauge functions instead of the powers of ε . This practice, which seems to assume that we have a valid series expansion without actual mathematical evidence, is sometimes objected to; but we will explain below the sense in which it is legitimate. The main problem consists in calculating the coefficients α_n , and our examples below show how this can be achieved recursively. This is why perturbation theory is sometimes defined as follows:

Perturbation theory is a large collection of iterative methods for obtaining approximate solutions to problems involving a small parameter ε . (Bender & Orszag, 1978, p. 319)

Note also that since we aim to obtain a truncated series approximation, we will fix the number of coefficients that we will solve for (N will often be only 1 or 2, in which case we will say, respectively, that we obtained a first-order or second-order solution).

In the third and final step, we set ε to the value that recovers the original problem we wanted to solve (often, it will be $\varepsilon = 1$) and just calculate the approximate solution by summing a finite number of terms of the perturbation series. That simple method very often works, but as we will see, sometimes more care is needed. We begin with an example in which it turns out to work well.

Consider the equation $x^5 + x - 1 = 0$. Our problem is to find a real root of this equation, that is, a value of x that satisfies this equation. The problem is hard, but we need not despair as we can use the method outlined above. Firstly, we introduce an ε as follows:

$$x^5 + \varepsilon x - 1 = 0 \quad (20)$$

We will choose to keep only two terms to obtain a first-order approximation. We thus assume that our truncated series solution will have the form $x(\varepsilon) = a_0 + a_1 \varepsilon$. We substitute this expression in Equation 20:

$$(a_0 + a_1 \varepsilon)^5 + \varepsilon(a_0 + a_1 \varepsilon) - 1 = 0 \quad (21)$$

We expand the fifth-power term using Pascal's triangle:

$$(a + b)^5 = a^5 + 5a^4b + 10a^3b^2 + 10a^2b^3 + 5ab^4 + b^5 \quad (22)$$

After gathering like terms, we obtain

$$a_0^5 - 1 + (5a_0^4 a_1 + a_0) \varepsilon + (10a_0^3 a_1^2 + a_1) \varepsilon^2 + O(\varepsilon^3) = 0. \quad (23)$$

hiding the complicated higher-order terms in the O -symbol (we do not need them anyway, since the ε^2 term will already fail to be 0 with this first-order approximation). We then match the coefficients of matching powers of ε on the left-hand side and the right-hand side. Since all coefficients of ε on the right-hand side are 0, we obtain the following equations for the first two coefficients:

$$a_0^5 - 1 = 0 \quad (24)$$

$$5a_0^4 a_1 + a_0 = 0 \quad (25)$$

Since we were interested with the real root of this equation, we obtain the value $a_0 = 1$ from Equation 24 and $a_1 = -1/5$ from Equation 25. We see that the solution of the coefficients is a recursive process that is in itself a purely mechanical task that presents no essential mathematical difficulty, provided the zeroth order equation, which is generally nonlinear, can be solved.

Thus, our approximate solution, which we denote $z(\varepsilon)$ in contrast with the exact but unknown solution $x(\varepsilon)$, can be written as follows:

$$z(\varepsilon) = 1 - \frac{\varepsilon}{5} \quad (26)$$

Notice that in Equation 20, if we set $\varepsilon = 1$, we obtain our original unperturbed problem. Thus, our approximate root will be $z(1) = 1 - 1/5 = 0.8$; it does not compare too badly with the exact solution, which is 0.755 rounded to three digits. If we were to do a bit more work, we would find that 2; accordingly our second-order approximation would be 0.76, even better!

Notice that we have provided no evidence to justify any step in which we assumed that the root $x(\varepsilon)$ of Equation 20 can be meaningfully written as an infinite power series. But in fact, we have

made no such assumption! The approach here can be justified by an explicitly finite approach borrowed from numerical analysis that in many cases allows physical interpretation, based on the concept of *residual* (see, e.g., Corless & Fillion, 2013).

The idea is quite general; the unknown function $f(\varepsilon)$ usually satisfies a known equation $\Phi(f; \varepsilon) = 0$ by definition (above, we had $\Phi(f; \varepsilon) = \Phi(x, \varepsilon) = x^5 + \varepsilon x - 1 = 0$). However, if we evaluate Φ using z instead of x , we wouldn't obtain 0 since z isn't the exact solution. The residual Δ is the quantity we obtain once we substitute the exact function $f(\varepsilon)$ by its truncated series approximation:

$$\Delta := \Phi \sum_{k=0}^N a_k \varepsilon^k, \varepsilon \quad (27)$$

Then z satisfies

$$\Phi(z; \varepsilon) - \Delta = 0,$$

not $\Phi(z; \varepsilon) = 0$.

In general if we correctly identify the first $N + 1$ coefficients, we obtain a residual that satisfies

$$|\Delta| = O(\varepsilon^{N+1}) \quad (28)$$

as $\varepsilon \rightarrow 0$. As we have explained, the symbol $O(\varepsilon^N)$ is conveniently used to refer to a function that decays like ε^N without having to specify it explicitly. In the example above, we implicitly used the notion of residual to find coefficients that guarantee that Equation 28 will be satisfied, that is, that the residual will be of higher order than the terms that are part of our approximate solution. Instead of writing Equation 23, we could more exactly have written our equation for the residual,

$$\Delta = a_0^5 - 1 + (5a_0^4 a_1 + a_0) \varepsilon + (10a_0^3 a_1^2 + a_1) \varepsilon^2 + O(\varepsilon^3), \quad (29)$$

and by an iterative inspection of the formula, we find that choosing $a_0 = 1$ guarantees that the residual is $O(\varepsilon^2)$ irrespective of the other coefficients, and that in addition choosing $a_1 = -1/5$ guarantees that the residual is. For small ε , this z is the exact solution of nearly the right equation. By doing more work, but using no new ideas, we may find $z_N = a_0 + a_1 \varepsilon + a_2 \varepsilon^2 + \dots + a_N \varepsilon^N$ for any fixed $N \geq 1$ with $\Delta_N = z_N^5 + \varepsilon z_N - 1 = O(\varepsilon^{N+1})$,

which can be made arbitrarily small by taking ε arbitrarily close to 0. Also, for this example, more is true. We may in this case take $N \rightarrow \infty$, and find an explicit formula for all a_k , thereby giving an infinite series—which turns out to be convergent—and the exact root. But that is no longer perturbation theory.

The question of which number N of terms is best can be answered easily: N is best when the magnitude of the residual $|\Delta|$ is smallest. Then, the error $|z - x|$ satisfies the inequality

$$|z - x| \leq \kappa |\Delta| \quad (30)$$

and $|z - x|$ will also be smallest. Here, κ is the condition number of the problem (see, e.g., Corless & Fillion, 2013), a quantity that is essentially a bound on

$$\left| \left(\frac{\partial \Phi}{\partial x} \right)^{-1} \right| \quad (31)$$

Singular Perturbations

A regular perturbation problem may be regarded as one for which the character of the solution set to $\Phi(f, 0) = 0$ is the same as the character of the solutions to $\Phi(f, \varepsilon) = 0$ for small ε . A singular perturbation problem is one for which the character changes discontinuously at $\varepsilon = 0$ (*mutatis mutandis*, $t = \infty$). The position of the perturbation parameter may play a key role in determining whether a perturbation is regular or singular, as these examples show:

Regular	Singular
$x^2 - 1 - \varepsilon = 0$	$\varepsilon x^2 + x - 1 = 0$
$y'' + \varepsilon y' + y = 0$	$\varepsilon y'' + y' + y = 0$
$y(0) = 1, y(1) = -1$	$y(0) = 1, y(1) = -1$

There are various definitions of singular perturbation problems in the literature, such as the one by Carl Bender and Steven Orszag (1978): “We define a singular perturbation problem as one whose perturbation series either does not take the form of a power series, or, if it does, the power series has a vanishing radius of convergence” (p. 324). They also use the more suggestive language: “[In either case], the exact solution for $\varepsilon = 0$ is *fundamentally different in character* from

the ‘neighbouring’ solutions obtained in the limit as $\varepsilon \rightarrow 0$.”

But this slippery distinction may not always be critical for understanding. Indeed, one common technique for solving so-called singular perturbation problems is to transform them (e.g., by change of variable) into regular perturbation problems. Interestingly, following this characterization, problems with spurious secular terms in the regular expansion display some aspects of both regular and singular perturbation problems (more on this in the example of Equation 45).

As a first singular example, consider $\Phi(x, \varepsilon) = \varepsilon^4 x^5 + x - 1 = 0$. This is a prototypical singular perturbation problem. For $\varepsilon \neq 0$, there are five (complex) roots. However, for $\varepsilon = 0$, there is only one, namely $x_0 = 1$. The character—the number of roots—has changed.

We may find the root near $x = 1$ by the same method as the previous example: let $z(\varepsilon) = a_0 + a_1 \varepsilon + a_2 \varepsilon^2 + a_3 \varepsilon^3 + a_4 \varepsilon^4 + a_5 \varepsilon^5$ and set as many coefficients of powers of ε in $\Delta = \varepsilon^4 z^5 + z - 1$ to zero as possible. This gives $z = 1 - \varepsilon^4 + \dots$ (implicitly stopping at some finite N). The other roots are more interesting. To find perturbation series for them, we transform to a regular problem, by using the change of variable $y = \varepsilon x$. Multiplying the original equation by ε gives

$$\varepsilon^5 x^5 + \varepsilon x + \varepsilon = 0 \quad (32)$$

and doing the change of variable gives

$$y^5 + y - \varepsilon = 0 \quad (33)$$

This is a regular perturbation problem for y , with five roots. By the same method as before, perturbation series for each can be found:

$$y_k(\varepsilon) = e^{(2k+1)\pi i/4} + \frac{1}{4e^{(2k+1)\pi i} + 1} \varepsilon + O(\varepsilon^2) \quad (34)$$

for $0 \leq k \leq 3$ and $y_4(\varepsilon) = \varepsilon - \varepsilon^5 + O(\varepsilon^9)$, giving

$$x_k(\varepsilon) = \frac{e^{(2k+1)\pi i/4}}{\varepsilon} + \frac{1}{4e^{(2k+1)\pi i} + 1} O(\varepsilon) \quad (35)$$

and

$$x_4(\varepsilon) = 1 - \varepsilon^4 + O(\varepsilon^8) \quad (36)$$

as perturbation series solutions for the original (singular) perturbation problem. Notice in this case that four of the solutions go to (complex) infinity as $\varepsilon \rightarrow 0$, leaving only the root near 1

being finite. This observation gives us some geometrical understanding of the reason for which this perturbation problem is singular.

Now, let us examine a problem that turns out to be well-behaved even though we may superficially expect a singular behavior. Consider

$$I(\varepsilon) = \int_0^{\infty} \frac{e^{-x}}{1 + \varepsilon x} dx \quad (37)$$

This integral exists for $\varepsilon \geq 0$. $I(\varepsilon)$ can be expressed in terms of special functions (so-called exponential integrals) but a simpler expression of its behavior for small ε would be helpful. Naive manipulations give

$$\frac{1}{1 + \varepsilon x} = 1 - \varepsilon x + (\varepsilon x)^2 + \dots \quad (38)$$

by the geometric series, so that

$$I(\varepsilon) = \int_0^{\infty} (1 - \varepsilon x + \varepsilon^2 x^2 + \dots) e^{-x} dx, \quad (39)$$

suggesting that

$$\begin{aligned} I(\varepsilon) &\doteq \int_0^{\infty} e^{-x} dx - \varepsilon \int_0^{\infty} x e^{-x} dx + \varepsilon^2 \int_0^{\infty} x^2 e^{-x} dx + \dots \\ &= 1 - 1!\varepsilon + 2!\varepsilon^2 + \dots \end{aligned} \quad (40)$$

It may seem remarkable that these naive manipulations, walking over the precipice of divergence for $|x| > 1$ as they do, manage to give useful perturbative expansions for $I(\varepsilon)$. Let us do these manipulations more carefully to see why. Note that

$$\frac{1}{1 + \varepsilon x} = \frac{1 - (-\varepsilon x)^{N+1}}{1 - (-\varepsilon x)} + \frac{(-\varepsilon x)^{N+1}}{1 + \varepsilon x} \quad (41)$$

for all x such that we avoid the singularity as $\varepsilon x = -1$; if we restrict $\varepsilon > 0$, then $1 + \varepsilon x \geq 1$ for $x \geq 0$ so division by zero never occurs. Now,

$$\frac{1 - (-\varepsilon x)^{N+1}}{1 - (-\varepsilon x)} = 1 - \varepsilon x + \varepsilon^2 x^2 - \dots + (-\varepsilon x)^N \quad (42)$$

is the sum of the *finite* geometric series, so

$$I(\varepsilon) = \int_0^{\infty} \left(\sum_{k=0}^N (-1)^k \varepsilon^k x^k \right) e^{-x} dx + \int_0^{\infty} \frac{(-\varepsilon x)^{N+1} e^{-x}}{1 + \varepsilon x} dx$$

$$\begin{aligned} &= \sum_{k=0}^N (-1)^k \varepsilon^k \int_0^{\infty} x^k e^{-x} dx + \int_0^{\infty} (-\varepsilon)^{N+1} \frac{x^{N+1} e^{-x}}{1 + \varepsilon x} dx \\ &= \sum_{k=0}^N (-1)^k \varepsilon^k k! + (-1)^{N+1} \varepsilon^{N+1} \int_0^{\infty} \frac{x^{N+1} e^{-x}}{1 + \varepsilon x} dx \end{aligned} \quad (43)$$

where all manipulations are of finite quantities and hence legitimate. Now, we do *not* let $N \rightarrow \infty$; rather, we look at $\varepsilon \rightarrow 0$. The term $\int_0^{\infty} \frac{x^{N+1} e^{-x}}{1 + \varepsilon x} dx$ is bounded (by $(N+1)!$) and hence the error term is $O(\varepsilon^{N+1})$ as $\varepsilon \rightarrow 0$, a term of higher order than all retained terms. Thus, this finite sum is a valid perturbation expression for $I(\varepsilon)$, in spite of the fact that if we were foolish enough to let $N \rightarrow \infty$, we would have a divergent series unless $\varepsilon = 0$, as can easily be seen for example by the ratio test.

As a practical matter, $I(0.01)$ can be evaluated quite accurately using only three terms of the series:

$$I(0.01) \doteq 1 - 0.01 + 2 \cdot 0.01^2 \doteq 0.9902 \quad (44)$$

The exact value is $I(0.01) = 0.9901942287$, so we see that we have obtained a very accurate answer with very little work. This exemplifies why convergence as $N \rightarrow \infty$ is of little or no importance in perturbation theory; what matters is that the finite perturbation series be continuous at $\varepsilon = 0$, indeed differentiable. Of course, this series is useless for large values of ε .

Finally, we discuss an example that illustrates the fact that problems whose perturbative solutions contain secular terms share features of both regular and singular perturbation problems. The equation

$$y'' + (1 - \varepsilon x)y = 0 \quad (45)$$

with initial conditions $y(0) = 1$, $y'(0) = 0$ is an example of a problem that is a *regular* perturbation problem on intervals $0 \leq x \leq X$ where $X = O(\varepsilon^{-\frac{1}{2}})$, that is, such that X is smaller than constant times $1/\sqrt{\varepsilon}$ when ε is small. Indeed, a regular perturbation expansion gives

$$\begin{aligned} y(x) &= \cos(x) + \varepsilon \left(\frac{1}{4} x \cos(x) + \left(-\frac{1}{4} + \frac{1}{4} x^2 \right) \sin(x) \right) \\ &\quad + \varepsilon^2 \left(\frac{1}{96} (21x^2 - 3x^4) \cos(x) + \frac{1}{96} (-21x + 10x^3) \right) \end{aligned}$$

$$\sin(x) \Big) + \varepsilon^3 \left(\left(\frac{35}{192}x^3 - \frac{35}{128}x - \frac{7}{384}x^5 \right) \cos(x) \right. \\ \left. + \left(\frac{35}{128} + \frac{7}{96}x^4 - \frac{35}{128}x^2 - \frac{1}{384}x^6 \right) \sin(x) \right) + O(\varepsilon^4)$$

However, inspection of this solution reveals that the residual of the truncated series is

$$\Delta = \frac{1}{384}x(-105\sin x - 70x^3\cos x - 28x^4\sin x \\ + 105x\cos x + 105x^2\sin x + 6x^5\cos x \\ + x^6\sin x)\varepsilon^4 + O(\varepsilon^5)$$

which contains a term $\varepsilon^4 x^7 \cos(x)$ when expanded. Since $z'' + (1 - \varepsilon x)z - \Delta = 0$, this is a *small* perturbation of the original equation only when $\varepsilon^4 x^7 \cos(x)$ is small compared to $-\varepsilon x \cos(x)$; hence $\varepsilon^3 x^6 \ll 1$ or $x \ll \varepsilon^{1/2}$. However, outside of this interval, the effects of the perturbation can be arbitrarily large, and so the problem would be considered singular in that region.

By using various methods that consist in rescaling the problem to eliminate the secular terms, such as Lindstedt's method, renormalization, or multiple scales, we can find an improved solution which is hardly more complicated,

$$z = e^{\varepsilon x/4} \cos\left(x - \frac{\varepsilon t^2}{4}\right) + O(\varepsilon^2), \quad (46)$$

and it is valid for $0 \leq x \leq O(1/\varepsilon)$. Since $\varepsilon^{-1/2} \ll 1/\varepsilon$, this is an improvement. Some applied mathematicians think of these methods as being appropriate for 'singular' perturbations, and consider this and problems like it to be 'singular'. After all, the residual with the result from the regular perturbation method is not uniformly small as $\varepsilon \rightarrow 0$; it is only small on intervals not as large as $O(\varepsilon^{-1/2})$. Notice also that if $|x| > 1$, then the perturbation is itself not small.

Limitations

Perturbation methods are extremely powerful and apply in an incredibly varied array of situations. Yet, they have some limitations. A basic limitation of perturbations methods is that they

do not apply to discontinuous problems; at least, not unless they have been regularized (transformed into smoother problems). Also, the cost of computing the series may grow quite rapidly with the order of the expansion. We are aware of cases with cost growing exponentially with N if done naively; in many cases, this can be improved to polynomial cost, such as $O(N^4)$, but even so this can be expensive.

Perhaps more interestingly, the results are valid only in a (possibly very small) region about the expansion point ($\varepsilon = 0$); this can give sometimes only a very limited view of the full range of behavior of the model. But the main limitation is the fact that to find p_0 requires solving a nonlinear problem. In general this is always the hardest part. To use perturbation methods, one has to have an initial approximation $p_0 \phi_0(\varepsilon)$; the problem of finding each successive p_k for $k \geq 1$ thereafter is (usually) linear. These two limitations may be addressed separately using a technique known as *homotopy*, or continuation. This can be a numerical technique but is not necessarily so, and it is helpful in a broad collection of situations (see, e.g., Sommesse & Wampler, 2005)

Notes

1. The importance of this distinction has become an important topic of discussion in philosophy of science (see, e.g., Batterman, 2002).
2. This example illustrates convergence. Archimedes in fact demonstrated more, namely the existence of the unique number that we call π , by demonstrating that the perimeters of inscribed polygons ended to the same number. We could have used this example to illustrate perturbation theory itself, by noting that each p_k is a constructible perimeter of a perturbed figure.
3. For sequences of functions, one has to be concerned with the convergence being *uniform*; we will keep discussion of uniform convergence to a minimum but note its importance both in theory and in practice.
4. See Boyer (1949) for a nice history of calculus and Bell (2005) for a history of infinitesimals. It must be noted that many new approaches have revived the use of infinitesimals, such as nonstandard analysis (see, e.g., Robinson, 1966) and smooth infinitesimal analysis (see Bell, 2008).
5. Expansion at infinity is scarcely more difficult. One uses gauge functions that vanish ever more rapidly at infinity, and one typically uses another letter (say t).
6. Because asymptotic power series are unique, an asymptotic power series equal to zero must have each coefficients equal to 0 (see, e.g. Jeffreys, 1962, p. 6). This fact justifies Equations 24 and 25. Note in particular that convergence as $N \rightarrow \infty$ is not needed.
7. We borrow this example from Bender and Orszag (1978, p. 327).

PHENOMENALISM

Two principal schools of thought, empiricism and rationalism, arose out of the philosophical tradition of the Enlightenment period, and of these two

schools, phenomenism is directly derived from, and inspired by, empiricist theories of reality. While there are many nuances and variations in phenomenalist thought, phenomenism can be fundamentally described as a set of theories that maintain that an individual's experience of reality is not comprised of their direct apprehension of real, physical objects but is in fact comprised solely of sensory stimuli, or, *phenomena*, that cannot guarantee any knowledge or certainty with regard to a real and physical world.

This radically empiricist notion that the mind experiences reality only as a collection of sensory perceptions is to be sharply contrasted with the opposing theories of the rationalist Enlightenment philosophers, like Benedict (Baruch) Spinoza and Gottfried Leibniz, who held that reason, or thought, could be used as a tool to legitimately ascertain certain truths and facts about a real, physical world. The first modern theories of phenomenism were advanced by the Irish empiricist George Berkeley, which were then further developed and principally modified by later philosophers such as David Hume, Immanuel Kant, John Stuart Mill, Ernst Mach, and Bertrand Russell.

While all of the aforementioned philosophers deal with phenomenist theory in their respective philosophical works, they do so in different ways, to different extents, and with different results. Some of the theories of the phenomenist philosophers have theological implications or underpinnings, like those of George Berkeley, while others are based upon nontheological and more scientific worldviews, like those of Ernst Mach.

The Theorists and Their Concepts

George Berkeley

In contemporary circles, the Irishman George Berkeley (1685–1753) is regarded as one of the fundamental modern initiators of phenomenist thought. Berkeley's phenomenism is developed by his two main philosophical foundations: idealism and immaterialism. His idealism is based in his belief that physical objects are *mind-dependent* and exist only as an assemblage of ideas, while his immaterialism is based on his belief that there is no such thing as physical substances and that only mental substances exist. Of these mental substances, to him there are two: a finite mental substance and an infinite mental substance constituted by a divine being, God.

These notions form the basis for Berkeley's version of phenomenalism, which he termed *subjective idealism*, and which he employed to negate any certainty regarding the objective existence of objects. He accomplished this by way of declaring that the ideas within a mind are the sole things that can be understood as existing or having reality and that any knowledge or facts garnered about entities outside of the mind are baseless and without merit. Furthermore, Berkeley takes his immaterialism so far, in fact, that he maintains that when a sensory stimulus is no longer perceived, it no longer exists except in the infinite mental substance, or mind, of God. As mentioned earlier, this is the theological implication of Berkeley's phenomenalism, and considering his position as the Bishop of Cloyne, it is an idiosyncratic coalescing of his philosophical and theological concerns.

David Hume

The British-born David Hume (1711–1776) is widely regarded as one of the preeminent philosophers of the Western philosophical tradition, and his work, which dealt with phenomenalism, helped to cement his standing as one of the most distinguished philosophers of the empiricist philosophical tradition. Hume maintained that it is impossible to intellectually move beyond or outside of experience, which itself was merely composed of perceptions. Such intellectual conditions, in Hume's view, would promote only illusions as opposed to certainties. Likewise, Hume enlists his personal understanding of perceptions to negate the philosopher John Locke's conception of material substances, in that Hume claims they are only perceptions. Moreover, Hume critiques George Berkeley's phenomenalism by maintaining that any Berkeleyan examination of mental substances can only lead back to perceptions.

Hume uses his phenomenalism, based upon perceptions, as the keystone to the entirety of his philosophical theories. For instance, Hume's scathing critique on the law of causality is centered on his phenomenalism; he maintains that the rationalistic interpretation that every event must have a cause cannot support consequent judgments, since humans can only perceive perceptions, thus, they cannot piece together the necessary connection between an event and its cause. To Hume, the mind can only be

categorized as an assortment of perceptions, and therefore, there can be no rational knowledge garnered from outside of such perceptions. Hume's phenomenalism allowed him to examine how relations of ideas can be logically true, yet totally extraneous with regard to reality, and it allowed him to explain that individuals may gain knowledge through sensory experience, but that since every individual's experience would be different, one could gain knowledge only of perceptions.

Immanuel Kant

Born in Königsberg, Prussia (now Kaliningrad, Russia), Immanuel Kant (1724–1804) is nearly universally acclaimed as one of the most important philosophers of the modern era. Kant's great intellectual achievement was his ability to synthesize the two dominant philosophical traditions of his time, empiricism and rationalism, into his own personally devised *transcendental idealism*, which sought to utilize and simultaneously transcend both traditions. Kant's phenomenalism differs from Berkeley's stringent idealism in that he believes that *appearances*, or phenomena, are derived from, and point toward, the unknowable *things-in-themselves*, or *noumena*. As detailed in Kant's greatest work, *The Critique of Pure Reason*, Kant critiques Berkeley's idealism further by claiming that when one perceives something, it is a perception of an object as it appears to us, and not merely an idea.

Furthermore, Kant's phenomenalism is quite distinct from Berkeley's and Hume's phenomenalism in that Kant believes the temporal succession of phenomenal appearances is absolutely indicative of a noumenal, though unknowable, reality. Whereas Berkeley and Hume would negate such a notion by saying that an individual can only perceive their subjective ideas or perceptions, Kant believes that we can in fact perceive objects but only in their phenomenal appearances. According to Kant, there must be some noumenal reality that orders the phenomenal reality or else no phenomenal reality could appear. In this way, he is quite distinct from his other philosophical contemporaries who dealt with phenomenalism.

John Stuart Mill

John Stuart Mill (1806–1873) was a prodigious British philosopher who is critically acclaimed as

one of the most significant thinkers of the 19th century. While Mill studied and wrote about and worked on a wide array of philosophical and social issues, his philosophical foundations were strongly empiricist, and thus, his theories on phenomenalism arise out of his intellectual empiricism. Consequently, Mill believed that when an individual interacts with a physical object, they are subjected to an array of sensory stimuli. Furthermore, such interactions with physical objects can produce different sensations under different circumstances. Mill claimed that after repeated interactions with particular objects, we as humans come to expect certain sequences of sensations under certain circumstances. Thus, Mill's phenomenalism boils down to his notion that physical objects are composed of their consistent possibilities of sensation.

In other words, to Mill, physical objects are assortments of sensations that could, will, and do occur upon interaction. From the complex network of these sensations and their possibilities are derived the concepts of spatial dimensions, viewpoints, and other similar notions. So, in a sense, Mill's phenomenalism is as contingent upon experienced phenomena as it is upon the unexperienced possibilities of phenomena. Mill believed that the actualities and possibilities of phenomena are lawfully and regularly ordered, and thus, we can have provisional certainties regarding their occurrences; from these actualities and possibilities, we take collections of ideas and then construct inferences concerning our interactions with physical objects to the point that certain inferences become nearly unconsciously automatic.

Ernst Mach

Ernst Mach (1838–1916) was an Austrian theorist who made notable contributions to the fields of philosophy, physics, and psychology. Mach's phenomenalism is different from that of the previous phenomenalist theorists mentioned, in that Mach derives his phenomenalism more from his scientific and psychological understanding than from any philosophical position. Still, the result is similar, for Mach was supremely interested in how the physical body digests, or processes, sensory stimuli. Through an intensive study of the human retina, Mach deduced that the mind does not apprehend stimuli directly but

rather through an embodied network of neural relations. As a consequence, Mach maintains that one does not experience reality firsthand but only its aftereffects that result from our nervous system's processing of it.

Thus, Mach's phenomenalism can be described by his belief that we do not encounter reality directly but rather through the organic construction of it as a result of the neurologic processing of sensory data. In this way, it can be seen how Mach's scientific and psychological background informs his phenomenalist conception of the mind. An important result of Mach's phenomenalism is that it seems to negate philosophical representationalism, in that it seems to make a straight bridge between appearance and reality unsustainable.

Bertrand Russell

The British philosopher Bertrand Russell (1872–1970) is regarded as one of the principal initiators of the analytic philosophical tradition and one of the most important thinkers of the 20th century. Russell's phenomenalist theories are similar to John Stuart Mill's phenomenalism, in the sense that Russell believed that our perceptions of sensory stimuli are not produced by physical objects but instead actually comprise them. In this way, to Russell, physical objects *are* sensory stimuli and not simply something that causes them. The difference between Russell's and George Berkeley's conceptions of phenomenalism, respectively, is that Russell believed that if a consciousness is removed from a particular set of sensory stimuli, there would still be a perspective from which to perceive such stimuli, whereas in a similar situation, Berkeley would maintain that the stimuli all but ceases to exist except in the mind of a divine being.

To describe this phenomenalist conception of reality, Russell utilizes the terms *private space* and *perspective space*. Private space can be designated as the perspective in which a single consciousness comes to perceive sensory stimuli, while perspective space can be defined as the totality of perspectives in which a multitude of private spaces interact and intersect. For Russell, different perspectives provide different aspects of the sensory stimuli that comprise physical objects.

PHILOSOPHY OF MIND

Philosophy of mind is a branch of philosophy concerned with the nature of mental events and processes. Inquiries into philosophy of mind can be traced back to ancient Greece, whereas interest in the nature of the mind can be found in many of the world's religions. Contemporary philosophy of mind is largely an interdisciplinary effort. Many contemporary philosophers of mind draw from work in computer science, neuroscience, psychology, biology, sociology, physics, and chemistry. However, a growing number of contemporary philosophers of mind have begun to borrow insights into the mental from other branches of philosophy such as phenomenology, existentialism, pragmatism, and postmodernism.

Contemporary work in the philosophy of mind varies in scope. As will be seen in what follows, many contemporary philosophers of mind work on local issues of mind such as the nature of mental content, the nature of the self, free will, emotion theory, and perception. Other contemporary philosophers of mind work on the nature of consciousness, the place of consciousness in nature, and the relationship between consciousness and the body.

Approaches to the Metaphysics of Mental Phenomena

At the most global level and in its most common manifestation, philosophy of mind attempts to provide a framework for understanding the place of consciousness in nature, the relationship between mental processes and other natural processes, and the nature of mental phenomena in general. Often, research on these issues is conducted within a particular theoretical paradigm that contains several key tenets, or positions, on the nature of mental phenomena. For most of these paradigms, the salient tenets of that paradigm

are derived from a number of key methodological and other metaphysical commitments. The following sections summarize many of the prevailing perspectives on the metaphysics of mental phenomena.

Brain State–Mental State Identity Theory

The *brain state–mental state identity* (BSMSI) theory maintains that, although perhaps conceptually distinct, mental states, or processes, are identical to states, or processes, in the brain. As an analogy for their position, early advocates of the BSMSI, or identity, theory evoked the relationship between lightning and an electrical discharge. Just as lightning is nothing more than an electrical discharge, the advocate of the BSMSI theory held that conscious phenomena are nothing more than various brain processes. Early advocates of the view hoped to clarify their position by drafting a distinction between *meaning* and *reference*. According to these thinkers, two terms may differ in terms of meaning, but not differ in terms of reference. On this view, the difference between mental states and brain states could be mapped onto a difference in the meaning of the terms, even though the terms shared a referent. So, in the case of lightning and electrical discharge, lightning and electrical discharge have different meanings even though they refer to the same phenomena.

Most advocates of the identity theory endorse methodological reductionism, understood as the collapse of one set of theoretical terms into another. To accomplish this reduction, proponents of this type engage in a three-part process. In the first part, the proponent seeks to clarify, or individuate, terms from folk psychological language (consciousness as it is described by the *folk*). In the second part, the proponent seeks to clarify, or individuate, terms from various brain sciences. In the third part, the proponent seeks to fix references between the two terms. Successful reference fixing should mean that the terms taken from the folk psychological language and the relations between them may be describable solely in the terms and relations provided by the brain sciences.

Mental State Eliminativism

The eliminativist's view of mental processes shares much in common with the proponent of identity theory insofar as the eliminativist views the mental processes as nothing other than various physical processes of the brain. Where the eliminativist makes breaks from the identity theorist is in the disavowal of folk psychology entirely. While the identity theorist retains folk psychology as a critical component of the reference-fixing process, the eliminativist maintains that folk psychology is so deeply erroneous that the inclusion of folk psychological terminology would not only hinder the development of a successful theory of mind but also point the theorist in the entirely wrong direction. That is, the eliminativist not only maintains that folk psychology is deeply flawed, but that folk psychology is mistaken about the kinds of mental phenomena that there are. So, for example, folk psychology generally progresses on the assumption that things like beliefs, emotions, desires, and so on are posited as true mental phenomena. The eliminativist may hold that none of these phenomena actually exists, and thus that any attempt to make a biological account of brain processes cohere with these phenomena is deeply misguided. Of course, it is important to note that a number of theorists, including those who would not describe themselves as eliminativists, challenge certain assumptions of folk psychology. The difference between these individuals and full-fledged eliminativism is a matter of degree.

Because the eliminativist disavows folk psychology entirely, the eliminativist cannot judge, as the identity theorist can, the success of a project on the basis of its reference-fixing success. Here, the eliminativist is aided by the methodological commitments of a particular scientific program. That is, to judge the success of an account, the eliminativist need only appeal to the demands of its theoretical paradigm. So, for example, an eliminativist constructing a neurobiological account of some particular phenomena need only judge the success of such an account in regard to the theoretical desiderata of neurobiology. If the account meets the desiderata, then the eliminativist can consider such an account successful. If the

account does not meet the desiderata, then the eliminativist must deem such an account unsuccessful. Again, the critical point of emphasis is that the eliminativist need not judge the success of an account on its ability to accommodate folk psychological phenomena such as beliefs or desires.

Functionalism

Functionalism is the view that a mental state, or process, cannot be defined in terms of that state's constitution but must be defined in terms of the role it plays within the overall system in which it operates. Typically, functionalists take a mental state, or process, to be determined in virtue of its standing in specific causal relations between itself, sensory information, other mental states, and behaviors. Functionalism, so construed, supports the intuition that constitutionally diverse systems may instantiate, or realize, identical mental states. So, for a simplified example, a functionalist may conceive pain as having the function of producing agitated states, be they agitated mental states or physical behaviors, and thus conceive both humans and canines as capable of being in the mental state pain without having to posit underlying identical substrates. That is, a human and a dog may both be in pain, even though a human's pain may be caused by the firing of C-fibers, and dog pain may be caused by some other source.

Although functionalism was formulated and defended by thinkers as early as the Scholastics, contemporary functionalism is very much indebted to the work of the English mathematician and computer scientist Alan Turing (1912–1954). On Turing's view, intelligence could be measured against other assumed intelligences, such as the intelligence of a human, by determining whether a particular system was capable of producing intelligible responses to particular queries formulated by the assumed intelligence. Today, this sort of measure is known as a *Turing test*, but its crucial contribution to philosophy of mind was the identification of thoughts with various functional roles, which, in the case of the Turing test, would be the system's ability to produce other internal states and appropriate responses.

The contemporary equivalent of Turing's view is called *machine state functionalism*. On this view, any minded creature's operations can be fully specified by the following instruction: If a machine is in state S_i and receives input I_j , then the machine will enter state S_k and produce output O_l . However, because the machine state view equates a mental state with the *total* state of the system, and many assumed intelligent systems, such as humans, appear capable of supporting complex but distinct internal states, many contemporary functionalists opt for another variety of functionalism.

One particularly popular contemporary view is sometimes referred to as *psycho-functionalism*. For the proponent of *psycho-functionalism*, the main point of departure between this view and the machine state functionalist's view is the psycho-functionalism's disavowal of Turing's instruction. Instead, the psycho-functionalism adopts the methodology of cognitive psychology and instead characterizes mental states in virtue of their role in a particular psychological theory. So, on the view of psycho-functionalism, a particular organism is in state M , if M is specified by some theory T and M plays functional role F as specified by T . However, many contemporary functionalists now defend carefully nuanced views that may not be easily described as either machine state functionalism or psycho-functionalism.

Embodied Cognition

Embodied cognition is the view that the mental states, or processes, of an agent are both causally and constitutionally dependent on that agent's bodily characteristics. Proponents of *embodied cognition* may be placed on a continuum of decreasing emphasis on the brain in cognition such that proponents of another approach to the study of mental phenomena may also be considered to be, at least in part, dedicated to the embodied cognition research program. Nevertheless, the majority of researchers self-described as proponents of embodied cognition typically also perceive themselves as combating the notion that cognitive processing may be described in abstraction from bodily mechanisms. These thinkers

stress the use of the environment by an agent to abet cognitive processing and the informational role of bodily feelings in cognitive processing while maintaining that phenomenal consciousness of an agent, what it is like to be that agent, does not extend beyond the skin, or other theoretical border, of the agent.

Although embodied cognition has generated significant interest in the past two decades, traces of the view can be found in St. Thomas Aquinas. On Aquinas's view, the soul, or mind, of an agent is considered as the form of that being. Contemporary advocates of embodied cognition share the monist understanding of the relationship between the mental and the physical with Aquinas and generally market their view as a radical departure from the homuncular understanding of the mind proponents of this view charge dualists, functionalists, and identity theorists with employing.

Typically, proponents of embodied cognition stress the importance of sensory-motor skills in accomplishing various cognitive feats such that an agent is thought to structure their world. Thus, proponents of embodied cognition challenge the division other approaches to the study of mental phenomena construct between the features of the external world the representation of those features internal to the agent in virtue of the division's inability to accommodate the extensive feedback loop that exists between the agent-world coupling. In the view of embodied cognition, knowledge emerges in the dynamic interaction between an agent and the environment such that an agent creates its world through its embodied actions. One crucial implication of embodied cognition, then, is that whether or not an agent possesses certain cognitive capacities depends on the material constitution of that agent. On this view, an agent having hands, legs, and eyes, as well as the skill to coordinate these body parts, may very well determine the kinds of intellectual feats that the agent is capable of.

Extended Mind Theory

Extended mind theory shares much in common with several key tenets of the embodied

cognition view. Where the extended mind theory deviates from embodied cognition is in its commitment to the position that the phenomenal consciousness of an agent, what it is like to be that agent, may extend beyond the boundaries of that agent's body. However, this is not to suggest that proponents of the extended mind theory do not recognize the importance of an agent's body in cognition. Rather, many proponents of extended mind theory often argue that a proper understanding of the dynamic interaction between the agent and the environment points not just to the recognition of the importance of the agent's body in cognition but even further to the recognition that cognition cannot be described as either internal or external to the agent. For example, embodied cognition theorists often defend their position through an appeal to the apparent coupling between visual perception systems and other sensorimotor capacities in particular environments. Extended mind theorists argue that coupling between the visual systems and other sensorimotor capacities, which the embodied cognition theorist takes as indicative of their both sharing in the constitution of the mind, is not much different from the coupling between the agent's body and the environment. If coupling indicates shared constitution, then the extended mind theorist argues that the environment must play a constitutional role in an individual's mind as well.

Panexperientialism

Panexperientialism is the view that all real relations in the world may, at some level, be described as mental properties. Panexperientialism is to be distinguished from the view of naive panpsychism, which holds that every real entity has a mind. Rather the panexperientialist maintains that the ultimate constituents of reality are most appropriately described in terms of phenomenal, that is, *felt* sensations. The panexperientialist conceives more complex-minded creatures, such as animals, as particularly arranged collections, or loci, of these phenomenal properties. Importantly, panexperientialists differ as to how these fundamental properties may be arranged and how their

arrangement may account for the apparent variation in differently minded creatures.

Although panexperientialism is a minority view in both the philosophical and scientific communities, the view has precedent in philosophical history. A version of panpsychism was defended in the early modern period by Gottfried W. Leibniz (1646–1716), and more recent views have been defended by so-called *process philosophers*, the most notable of which are Charles Hartsorne (1897–2000) and Alfred North Whitehead (1861–1947). While the latter two hold distinct views from Leibniz, all three employ a similar and commonly evoked argument in support of their view. On this account, the macroscopic world is a sort of record of a microscopic reality such that any explanation given in the microscopic reality must be illustrated in the macroscopic world. At some point, these thinkers claim, the explanation must bottom out and the question becomes one concerning the nature of what we might call ultimate individuals. These thinkers' answer is that the illustration we must find in the macroscopic world need be neither visual nor tactile. Rather the answer itself is given in experience. At any moment in time, our experience reveals itself as individual; anything which is an object of awareness is always presented to an individual. Thus, the nature of the ultimates, panpsychists argue, is experiential.

Other panexperientialists argue along more theoretical, but similar, lines. In this view, mental properties are identified as intrinsic, or nondispositional, properties, while the properties of contemporary science are identified as relational, or dispositional, properties. Given the conviction that relational properties cannot exhaust the set of real properties, the panexperientialist argues that the nondispositional properties which enter into the relations identified by contemporary science must be the phenomenal properties the panexperientialist claims that experience tells us are intrinsic. Thus, for these theorists, a proper account of more complex cognition, such as human cognition, must cut across many (if not all) of the domains of contemporary science. However, it is worth noting that panexperientialists may support their arguments in a number of other ways and incorporate elements of many of the other approaches to the study of mental phenomena.

Neutral Monism

Neutral monism is the view that there are intrinsic, nondispositional, fundamental properties in reality and that these properties may enter into relations, which may be described as either mental or physical. An early version of this view was defended by the Dutch philosopher Baruch Spinoza (1632–1677). In Spinoza's view, both an agent's mind and body are manifestations of an underlying neutral substance. In the early 20th century, views of this sort were defended by both William James (1842–1910) and Bertrand Russell (1872–1970). Although the view shares much in common with panexperientialism, neutral monism may be distinguished from panexperientialism insofar as neutral monism sees the fundamental constituents of reality as neutral, while the panexperientialist sees the fundamental constituents of reality as primitive mental properties.

Dualism

Dualism is the view that mental phenomena are a distinct type of thing from other physical phenomena. Typically, the view is formulated on several key distinctions, such as the distinction between observable and unobservable properties, intentionality and nonintentionality (i.e., whether an object is about something); extension and nonextension, where mental phenomena are considered unobservable, intentional; and nonextended and physical phenomena are considered observable, nonintentional, and extended. (It should be stressed, however, that some dualists deny mental phenomena must necessarily have each of these properties.)

Dualism has a long history in the philosophical canon. An early example of the view was defended by the ancient Greek thinker Plato in the *Phaedo*. There, Plato argued that the soul must be immaterial from his doctrine of Forms, which he contended not only govern all of reality but render it intelligible and is itself immaterial. Assuming that to perceive a Form, the intellect must share something in common with the Form, Plato argued the soul must be itself immaterial. Some scholars attribute a similar argument to Aristotle. According to these scholars, in the *De Anima*, Aristotle argued that the soul must be immaterial because it has no restricted range of objects which it may consider, and every faculty

which corresponds to a material organ, such as sight, sound, and touch, have a restricted range of objects they can receive.

However, the most common form of dualism, *substance dualism*, is first attributed to the early modern French philosopher René Descartes (1596–1650). In this view, mental phenomena are properties of a substance, distinct from the physical properties of a human's body. Moreover, this view generally maintains that a person is to be identified with the mental substance rather than the physical substance or the joint mental–physical entity.

In the modern period following Descartes, and even to this day, dualism has generally been dismissed on the basis of its inability to give an account of how two distinct substances can interact. Some contemporary proponents of the substance view of dualism counter this objection with the reply that one cannot rule out a priori the interaction of two distinct substances. They accept the interaction objection and instead opt for a more naturalistic version of dualism, which has been proffered under the name *double aspect theory* or *property dualism*.

In the double aspect view, mental and physical properties are different properties of one underlying fundamental type of entity. Although double aspect theory shares much in common with neutral monism, the view is to be distinguished from the latter in that neutral monism allows for fundamental constituents to express themselves as mental, physical, both, or neither while double aspect theory maintains that the mental and physical are inseparable, irreducible, but necessary properties of reality.

Despite the double aspect theorists' naturalistic take on dualism and their abandonment of the notion of distinct types of substances, double aspect theory has faced similar interactionist challenges as substance dualism. Like the contemporary substance dualists, some double aspect theorists object to the interactionist challenge. Others, however, accept the challenge and deny that such interaction takes place. One such group, the *epiphenomenalists*, maintain that the mental states of an individual have no bearing on the physical states of that person whatsoever and are merely *along for the ride*, in a manner analogous to the way the shadow cast by a speeding car in the sun is *along for the ride* with the speeding car.

Another group, *parallelists*, maintain that causation occurs within property types and that the parallel causation within each type merely runs parallel with the other type.

Central Issues in the Metaphysics of Mental Phenomena

Because interest in the nature of mental phenomena has permeated philosophy for centuries, many philosophers of mind have aimed not only to provide arguments in favor of their particular metaphysical stance but also to provide arguments against other prevailing metaphysical stances. Importantly, these negative arguments may be directed at a stance distinct from one's own, or at a stance similar to one's own. For example, a functionalist may not object only to dualism but also to other functionalist programs. The following is a brief presentation of some of the central issues debated in contemporary discussion on the metaphysics of mental phenomena.

Qualia

The term *qualia* has appeared in discussions on philosophy of mind for almost a century. It was first used by C. I. Lewis (1883–1964) in 1929 in a discussion of the sense-datum theory of perception. However, its contemporary use has been extended to refer to the properties of phenomenal experience, what it is like to have that experience, altogether. A singular property of a synchronic moment is called a *quale* and a number of these properties are called *qualia*. So, for example, the sight of a red book would involve one quale, what it is like to see the red book, and the sight of a blue book would involve another quale, what it is like to see the blue book, while both sensations are dubbed qualia.

At this level of description, the existence of qualia is uncontroversial. However, a number of contemporary philosophers have contended that qualia have the additional features of being non-representational, intrinsic properties of an experience. According to these theorists, qualia are accessible to introspection, mental properties corresponding to some salient property of an object, the sole determinant of the character of an

experience, and not covarying the representational content of the object to which the quale corresponds. Whether or not qualia truly possess these features, and to which mental states qualia correspond, has generated significant debate.

Within the discussion of qualia, there has been the debate over whether or not qualia are reducible to other physical properties. This issue has been of particular importance to the philosophy of mind because if qualia are not reducible to other physical properties, then the reductive approaches to the study of mental phenomena, such as the mental state–brain state identity theory, mental state eliminativism, and some versions of functionalism, must be flawed and incorrect. Central to this debate are a number of key characters and thought experiments including color-blind neuroscientists and philosophical zombies.

For example, some philosophers of mind have argued that a brilliant but color-blind neuroscientist with complete, exhaustive knowledge of the neurobiological mechanics of color perception would not know what it is like to see color, a phenomenon. Such philosophers further suggest that knowledge of physical truths therefore does not exhaust the knowledge of mental truths and thus that mental properties cannot be reduced to physical properties. Similarly, some philosophers of mind have argued that creatures physically identical to humans, but without phenomenal experience (philosophical zombies), are conceivable and that their conceivability demonstrates the irreducibility of mental phenomena to physical properties.

Content Internalism and Externalism

With the increasing popularity of the situated views of mental phenomena (embodied cognition and the extended mind theory and various versions of functionalism), contemporary philosophers of mind have become increasingly interested in the extent to which cognition represents an agent's world and how these representations gain their meaning or content.

According to *content externalists*, the meaning of an individual's concept is determined by the relationship between the individual and the

individual's environment. A classic thought experiment in support of this position considers two individuals whose mothers are identical twins and who are raised in isolation from one another, but in similar environments. When each individual expresses the statement "I want my Mom," the individual's wish will be satisfied only if the individual is brought the individual's mother and not an identical sister, even if the individual child does not know that the wish is not satisfied. So, the externalist argues, if individuals know what they mean and say what they mean, the difference between each individual's thought "I want my Mom" may not amount to a difference in the internal constitution of either individual.

Content internalists, on the other hand, maintain that the meaning, or content, of an individual's concept is determined by the various details of the individual's internal constitution. A content internalist maintains that the content of an individual's thoughts can be discerned by carefully observing the subject's mind, or if the content internalist endorses a reductionist view of mental phenomena, the substrate of the subject's mind. Other philosophers of mind argue that meaning is determined by both internal and external factors. For example, some philosophers of mind recommend two-dimensional semantics, which takes each concept to have both an external (sometimes called a *wide content*) component and an internal (sometimes called a *narrow content*) component.

PHILOSOPHY OF SCIENCE

All men are mortal.
 Socrates is a man.
 Therefore, Socrates is mortal.

Aristotle's syllogism arguably marks the beginning of formalized scientific reasoning. Linking a general premise ("all men are mortal") to a particular observation ("Socrates is a man") allows for the logical deduction of the conclusion: Socrates is mortal. Reflection on the structure and the methods of scientific reasoning touch on the central questions of the philosophy of science. Although its roots can be traced back to ancient Greece, as a subdiscipline of philosophy, it gained particular prominence only in the late 19th and during the 20th century, when scientific (and technological) progress turned science into the main source of knowledge and a driving force of social change. In the process of scientific development, in particular the formation of modern natural sciences, philosophy and science became more differentiated: While the latter focused on the observation and explanation of natural phenomenon and aimed at the development of theories and discovery of natural laws, the former began to reason on the foundations of scientific explanation. A second philosophical strand emerging as a reaction to the increase in importance of science was the ethics of science. It concentrates on the consequences of the expansion of science and the related technological progress, questioning ethical standards of research and the ramifications and potential dangers of scientific discoveries. In contrast, philosophy of science

focuses on the nature of scientific reasoning: What are scientific theories and methods? By analyzing the methods of inquiry as well as the explicit and implicit assumptions of scientific practice, philosophy of science deals with the fundamental epistemological question of what separates knowledge from belief.

Coming from the Latin word *scientia*, which means knowledge, philosophy of science seeks to answer the question of what scientific knowledge is. In a broad sense, knowledge can be defined as *justified, true belief*. The definition is especially suitable, for it highlights two important aspects of the question about the nature of science: (1) What qualifies a belief to be regarded as true? and (2) How can knowledge claims be justified? Another related, fundamental task is the identification and justification of reliable criteria to demarcate science from nonscience or pseudoscience. Demarcating science from nonscience thus puts philosophers of science in the midst of struggles over the respective authority of scientific and non-scientific knowledge and internal disputes about the relation of the natural and social sciences.

Principles of Scientific Reasoning

Observation

Scientific inquiry is based on observation and the collection of data for formulating and testing hypotheses and finding explanations. Observation can either be direct (x is accessible for measurement) or indirect (existence of x has to be derived from a theoretical framework). Furthermore, phenomena that are *in principle* unobservable (e.g., metaphysical entities) have to be separated from *not yet* observable facts. This basic conviction provides a first, tentative criterion for demarcating scientific from nonscientific knowledge: Science focuses on observables. Unobservable, especially metaphysical, questions, although important for science, are not part of scientific inquiry.

Theories and Methods

Scientific reasoning relies on theories and methods. However, the use of theories and methodological approaches is not sufficient to label a

particular insight scientific. Every observation requires a framework of assumptions to be explainable. The observation that the sun rises every morning in the east and sets every evening in the west, for instance, can give rise to a variety of concepts. One could link the apparent daily “birth” and “death” of the sun to the presence of gods, eventually developing elaborate beliefs, which require specific actions (e.g., prayers, sacrifices) to stabilize this cosmic rhythm. Moreover, theories can be false but still be scientific, while a belief can be true without being scientific. It is therefore necessary to differentiate between the structure of theories and methods on the one hand and the truthfulness of a claim on the other.

What is scientific theory? The classical Greek term *theoria* (θεωρία) literally means “viewing” or “looking at.” A scientific theory is an axiomatic system, which offers a specific point of view and explanation of selected phenomena of nature or the social world. Theories guide scientific inquiry and are important to determine which particular aspects of reality should be observed and analyzed. According to this understanding, scientific theories are not only explanatory models developed to explain observations already made. They represent conceptual frameworks, which help to select and interpret the phenomena that should be observed. Theories are mental models or perspectives, which highlight some characteristics while others are rendered irrelevant for explanation. In general, a theory can be described as a connected set of ideas and propositions. The ideas constitute the concepts (or conceptual ideas) of a theory. These provide an explanatory framework for a defined set of observations and allow the formulations of propositions and hypotheses, which are open for empirical testing. Empirical findings can either verify or falsify a theory. In order to gather such supporting or contradicting empirical evidence, *scientific methods* must be employed. This means that the results and interpretations of an observation must be (1) connected to the hypothesis in a distinct way, (2) comprehensible, and (3) repeatable.

The significance of scientific theories and methods depends on the overall aim of scientific inquiry. A rather simple approach, close to a commonsense understanding of theories, regards them as means to deduct “laws” to explain observed

correlations between particular phenomena. From an instrumentalist’s perspective, theories are more than a means of explanation; they are instruments for making predictions about a particular set of data, that is, a specific fraction of the natural or social world. Theories serve as information processing units. Observable data (input) are processed to generate observable predictions (output). The quality of a given theory in this view depends on its ability to generate predictions regarding what will be observed. The correctness of the predictions will ultimately prove the quality of the theory. Instrumentalism treats scientific theories as means to producing *justified, true belief*. Statements and propositions of a theory are truth-evaluable only if the predictions made on observable data turn out to be correct.

A major criticism of instrumentalism in science is the neglect of impalpable (unobservable) data. Impalpable data must not be juxtaposed with speculative data: Both the force of gravity and the concept of causality are impalpable, yet important for scientific explanation. Moreover, the distinction between observable and unobservable entities is not necessarily sharp or distinct. Improvement in observation techniques and advanced instruments (e.g., microscopes) can shift the boundaries between the two categories. In contrast to instrumentalist approaches, which hide those unobservable entities inside the black box of theories, scientific realism, while emphasizing that there are significant differences in the empirical claims about observable and unobservable data respectively, argue that both have to be considered.

Scientific realism is an umbrella term for positive epistemic approaches toward scientific theories. The overall assumption of scientific realism seems to be rather simple: It is based on the belief in the existence of a real outside world, which exists in a distinct way independently of scientific observation. In contrast to idealist or neo-Kantian approaches, which share the common belief that the experienced reality depends, at least partially, on observation and the mind of the observer (most prominently the Kantian belief, outlined in his famous *Critique of Pure Reason* that *causality* doesn’t exist in the outside world but is a category of human understanding), scientific realists state that theoretical claims themselves constitute knowledge about the world. In this sense, scientific

realism differs sharply from instrumental approaches, for its baseline assumption states that (the best) scientific theories can give true (or approximately) descriptions of the independent, outside world.

The Demarcation Problem of Telling Science From Nonscience and Pseudoscience

Defining scientific knowledge implies to label some knowledge as unscientific. However, this task is notoriously complicated since nonscientific reasoning and even bogus science share some common characteristics with science: Beyond intuitive distinctions between typical scientific fields (e.g., physics, biology, chemistry, or astronomy) and nonscientific fields (e.g., astrology, alchemy, or phrenology) defining satisfying criteria to justify this categorization is controversial. The importance of this problem is underlined by epistemological as well as practical reasons. In contrast to a mere agreement that some specific sets of lore (say, astrology) doesn't qualify for scientificity, philosophy of science raises the claim to explain what makes reasoning scientific. In the history of the philosophy of science, various criteria for the distinction of scientific and nonscientific knowledge have been proposed. A demarcation criterion close to a commonsense understanding of science was introduced by logical positivists such as Ludwig Wittgenstein (1889–1951) and Rudolf Carnap (1891–1970). In their view, scientific statements are meaningful as long and only as they are verifiable. Verification requires the empirical testability of a particular claim.

Karl Popper (1902–1994) suggested an opposing perspective: For him any scientific theory must be falsifiable. His principle of falsification rests on the conviction that the cardinal characteristic of scientific knowledge (which separates it from any other form of knowledge) is the fundamental possibility to prove it wrong. A radical departure from the principle of verification, his approach changed the way that scientific claims have to be formulated. In contrast to belief systems (e.g., religious convictions) as well as most pseudoscientific theories, scientific hypotheses must include clear criteria for their falsification. For instance, asserting a specific relation between an astrological star

sign and a person's character traits is not a scientific hypothesis.

The principles of verification and falsification represent the most common, yet not definitive, criteria for demarcating science from pseudoscience and nonscience. Popper's concept of falsification is widely used to test the scientific character of a given theory. To demand in-principle falsifiability is intuitively a plausible criterion: only theories whose assertions can be tested and falsified can lead to true scientific discoveries. Concepts that lead to general, untestable statements or theories—which can be made to fit any empirical observation—violate Popper's principle of falsifiability. Either the purported link between one's sign of the zodiac and one's personality must be empirically testable or astrology must be labeled as pseudoscience. Likewise, theories that tend to explain away conflicting data by inventing ad hoc explanations to maintain (or simulate) consistency with conflicting data also would not count as scientific. The criterion of falsification can be criticized, however, for being too simplistic. Especially complex theories that include sets of assumptions, hypotheses, and heuristics cannot easily be falsified. In these cases, falsification describes a process rather than a decisive moment when a theory is proven wrong. It is more likely that theories, when continually confronted with conflicting evidence, are running out of explanations. This may result in the *ex post facto* characterization of a theory as pseudoscientific but certainly doesn't necessarily offer the precise demarcation criteria as envisioned by Popper.

Scientific Reasoning: Induction and Deduction

The demarcation criteria of verification and falsification (roughly) correspond with two fundamental approaches of scientific reasoning: induction and deduction. *Inductive reasoning* seeks to derive general principles from individual observation, while the process of *deductive reasoning* starts with some general statements (premises) and aims at assigning logically certain conclusions for individual cases. Induction and deduction employ opposite logical modes of explanation. They have to be further qualified with regard to the principles of verification and

falsification and with respect to universal or probabilistic explanation respectively.

Induction and Hume's Problem

Inductive reasoning starts with specific observation so as to discover general rules or laws, which can be applied to a class of cases of the same kind. Observing a swan and noticing that it is white is one such observation. Additional observations (other swans of the same subspecies) may confirm that mature animals have this distinct color. However, a single observation of a black swan would refute the inductively derived conclusion "all swans are white."

The principles of verification and inductive reasoning are closely related. Linking the meaning of scientific knowledge to its verifiability poses a major problem, for then scientific laws could never be verified: In general, laws in science have the following logical expression:

For all X: if A then B

Observing B confirms A. The connection between A and B is only proven inductively, however, not conclusively. In a logical sense, the confirmation of the interrelation between A and B is necessarily provisional. Scientific laws are not strictly verifiable, for observing B at the time t allows only the confirmation of A_t . Consider the famous anecdote of Newton observing an apple (B) falling from a tree in a straight line. Let's assume that he concludes that the trajectory of the apple is determined by gravity (A) and let us further assume that he presumes some regularity (X). How could he verify his claim that the falling apple "proves" a law of gravity? From the perspective of logical positivism, he could observe more apples drop ($B_{t_1} \dots B_{t_n}$) to confirm the influence of $A_{t_1} \dots A_{t_n}$. In a strict sense, verification of the law of gravity would require the observation of all apples (and for that matter all other bodies) to fall. Arriving at a principle by complete observation is rarely possible. Nevertheless, scientific as well as everyday knowledge often rests on convictions gained inductively. In fact, most of reasoning depends on the assumption that unobserved objects are similar in all relevant aspects to objects

of the same class which have been examined. That means that we assume that our observations made "so far" can be generalized for similar unobserved objects in time and space. Distant objects (apples in a faraway country) will behave like the ones one could actually observe. The same is true for objects separated in time. An observation made today (all other things being equal) can be repeated tomorrow, and the day after tomorrow and so on. But can the premise that unobserved objects resemble observed objects in all relevant aspects lead to justified true belief? The 18th-century Scottish philosopher David Hume, who was first to address this problem, suggested the addition of this general premise to all inductively derived knowledge: He calls the underlying principle allowing the generalization of a proposition made from the observation of a subset of objects or cases the *uniformity of nature* premise. The uniformity of nature assumption is no insurmountable rational justification for induction. As stated earlier, knowledge can be defined as *justified true belief*. By invoking the uniformity-of-nature assumption, inductive reasoning cannot be justified in a strictly logical sense. Although we might have good reasons to assume that the "next" observable object (e.g., another apple about to fall from a tree) will behave in a way already observed, this claim is only tenable under the assumption that nature is nonrandom and sudden changes in the behavior of observable objects do not occur.

Hume's problem cannot be solved in a strictly logical sense. Instead of proving the uniformity-of-nature assumption, scientists usually try to pile up empirical evidence to enhance the plausibility of the belief. Hume pointed out that this strategy itself entails an inductive argument. Any attempt to increase the plausibility of the uniformity-of-nature assumption by arguing that observed evidence is a reliable guide to what can be expected in the future simply repeats the uniformity-of-nature argument.

From an inductive perspective, the observation of some falling apples never allows us to formulate general laws of gravity (in a strict logical sense) although the uniformity-of-nature assumption gives us good reasons to expect the next apple to fall.

Deduction and the Covering Law of Explanation

In contrast to inductive reasoning, *deductive explanation* rests on the assumption that conclusions regarding specific cases can be derived from general premises and laws.

Among the most influential claims about deductive scientific explanation is the so-called *covering law of explanation* (also referred to as *deductive-nomological* or D-N model) introduced by Carl Hempel and Paul Oppenheim in 1948. In order to be *sound*, any scientific explanation must satisfy logical as well as empirical conditions of adequacy. Most important, the explanandum must be a logical consequence of the explanans; that is, it must be logically deducible. Therefore the explanans must contain general laws and empirical (testable) content. Moreover, to satisfy the conditions of empirical adequacy, the laws and statements entailed in the explanans must be “true.” That means that all the relevant available evidence supports them. The formal structure of the deductive-nomological model resembles the Aristotelian syllogism:

The explanans consists of one or more scientific laws (L) and a set of specific conditions (C):

$$\begin{array}{l} L_1, \dots, L_n \\ C_1, \dots, C_n \end{array}$$

The explanandum (E) must be logically deducible from the explanans. The model rests on the operation of general laws and empirical particular facts. Scientific explanation in this model means to demonstrate that a particular phenomenon can be subsumed under a covering law. The deductive-nomological model of explanation demands universality in a strict sense. Explanation must cover *all* cases with specific conditions and aims at deriving laws and general theoretical principles. If the predicted connection between the explanans and the explanandum fails to materialize in *some* cases, according to the deductive-nomological model, we cannot speak of a scientific explanation of the phenomenon in question at all. But is such a model sufficient for all kinds of circumstances?

Medical doctors are accustomed, for example, to attach a mortality rate to a particular disease.

Statistically, a certain percentage of patients who are given a specific medical treatment will still succumb to a disease. However widespread in everyday scientific practice, examples like this beg the question whether scientific explanation must establish universal, logical connections (Y is always a consequence of X) or if probabilistic statements (Y is the likely consequence of X) are sufficient.

Probabilistic Explanation

Instead of establishing universal lawlike connections, probabilistic explanations state that if certain specified conditions are fulfilled, the probability of a particular occurrence can be measured. In this model, the explanans does not logically/deductively imply the explanandum. In other words, the truth of the explanans (e.g., the correct diagnosis of a specific disease) does not make the truth of the explanandum certain (e.g., the consequences may vary between individual cases/patients). The probabilistic-statistical model leaves room for doubt. Instead, depending on observation and statistical calculation, the explanans confers a certain degree of likelihood on the explanandum. Similar to the deductive-nomological model, probabilistic approaches presuppose some general laws (in this sense they are also nomological); but dissimilar to D-N models of explanation, laws are treated as statistical connections rather than universal, logically necessary regularities.

Induction and Probability

Probabilistic explanation is nomological because it presupposes the existence of general laws. In contrast to the D-N model, these laws are of statistical rather than universal form. As a result, the explanatory arguments, which can be derived from statistical laws, are inductive in character. Whereas in the deductive perspective, a particular question is (or is not) covered by a universal law, inductive explanation leaves room for varying numerical degrees of empirical confirmation. Actually, probabilistic arguments are used to justify inductive reasoning, because the reliability of inductive reasoning increases with the statistical probability of a particular observation. While

the observation of a black swan (as in the example above) would, from the perspective of deduction, falsify any inductively derived claim about the color of these kinds of birds, it can still be reasonable to adhere to the claim if statistical calculations confirm its reliability. If nine of 10 swans actually are white, it is reasonable to assume that (the vast majority of) swans are white, or to speak of swans as white birds. Additionally, probabilistic explanation underlines the practical importance of inductive reasoning. Most often science aims not only at developing justified true beliefs but also at practical knowledge. If, for instance, a particular treatment proves (statistically) effective in 80% of cases of a disease, it would be highly impractical to conclude that there is no treatment available at all, although its appropriateness had been disproved in two of 10 cases.

Explanation and Prediction

Deductive and inductive reasoning aim primarily at scientific explanation. In both perspectives, observation must come first. Prediction, in contrast, aims at making scientifically sound statements of yet-unobserved phenomena. However, giving explanations and making predictions respectively should not be conceived as rival perspectives only. In an instrumental understanding of scientific theorizing, the ability to predict specific outcomes can—even more than its ability to deliver explanations—be the touchstone of the quality of a theory.

In general, deduction employs a logical dualism in regard to prediction: If a “new” case is covered by a particular law, its outcomes can easily be predicted; if it is not, then nothing at all can be said about the outcomes. Inductive reasoning offers good reasons (given the uniformity-of-nature assumption) to expect a specific outcome, in case its likelihood can be derived from a statistical law. Deductive reasoning predicts the same outcomes as have been confirmed for a class of phenomena/cases $C_{1...n}$ covered by a (set of) universal law(s). Inductive reasoning derives the likelihood L for a new Case C_{n+1} from the statistical connection already observed in a number of cases $C_{1...n}$. The limits of scientific prediction, which also separate scientific prediction from

prophecy, are defined by the availability of existing observation.

In practice, scientific predictions are of paramount importance while at the same time posing a major problem for the philosophy of science. The main problem is that predictions, in particular with regard to issues such as global climate change or international health risks, are based on models. Despite the complexity of contemporary modeling exercises, which allow the inclusion of thousands of variables and interactions, such models present simplified versions of reality and often involve deliberate omissions and iterations of the underlying set of variables to test for variations that affect the probability of outcomes.

Scientific Progress, Revolution, Evolution, Programs, and Traditions

Science is not static. Moreover, scientific knowledge must not be treated as a treasure that is constantly increased. Also, the process of scientific knowledge production is not a teleological venture, continuously diminishing the amount of ignorance until everything shall be known. Hypotheses can be verified *or* falsified, and at times theories have to be abandoned or reformulated. The history of science gives plenty of examples of change, even dramatic change: The Copernican turn in the mid-16th century symbolizes such a paradigm shift, replacing the Ptolemaic model that put the Earth at the center of the universe, with the new, heliocentric worldview still in place today. Discovery of the natural element of oxygen by Antoine-Laurent Lavoisier in the second half of the 18th century provided a better explanation for the process of combustion, rendering the then predominant “phlogiston theory” obsolete and led the way to modern chemical science. Albert Einstein’s theories of special and general relativity, developed in the early 20th century, radically changed modern physics. When scientific knowledge is subject to change, sometimes fundamental change, how does science then proceed? An influential conceptualization was developed by the American philosopher Thomas Kuhn. In his view, scientific progress is characterized by periods of stability with an accepted set of established theories and scientific practices, and periods of

scientific “revolutions,” in which time-honored concepts and ways of approaching the world are abandoned and eventually replaced by (radically) new ideas, theories, and practices. During periods of stability, a scientific discipline can rely on an established set of theories, ideas, and methods. Scientific inquiry during such periods of stability is referred to as “normal science.” Central to this concept of normal science is the existence of a *paradigm*. A paradigm consists of some fundamental theoretical assumptions and concepts commonly shared by the members of a particular discipline, together with some successful applications of the theoretical concepts. In order to become paradigmatic and transmitted in the textbooks of a discipline, a theoretical concept must be evidentially suitable to solve some empirical problems within the respective field of research. A paradigm normalizes a scientific discipline in a way that it provides a firm theoretical foundation and simultaneously represents a unifying outlook of how further research should be conducted. Day-to-day activity in the modus of normal sciences consists of the explanation of particular problems by employing the agreed-upon theories and methods covered by the ruling paradigm. Consequentially, Kuhn invokes the metaphor of the revolution to describe the moment when the unifying consensus is challenged and the ruling paradigm is tackled. Much as in the case of political revolution, the first question that must be answered refers to the timing of a revolution. In Kuhn’s view, normal science is engaged with trying to solve minor problems without introducing substantial change to the paradigm. Over time, anomalies may occur; that is, problems apparently inexplicable by the ruling paradigm. A sense of crisis may emerge when the number of anomalies increases and/or the problems of explaining them are directly linked to core features of the assumptions and concepts commonly shared. Under these circumstances, confidence in the old paradigm is weakened. This process gives way to the emergence of radical new approaches. In Kuhn’s words, science enters a *revolutionary phase*. During this time of disorder, various competing concepts emerge, while the scientific community, now divided into factions, is trying to regroup and “normalize” their research activity. Eventually the

best available concept will win over the majority of the representatives of a discipline and become the new paradigm, signaling the beginning of a new stable period of normal science. In sum, scientific progress in this model is characterized by lengthy periods of normal sciences, punctuated by occasional revolutionary phases.

The theory of scientific revolution was widely acclaimed for its ability to explain moments of paradigmatic shift in science, as in the preceding examples. At the same time, alternative theories of scientific progress were developed to cope with the apparent shortcomings of Kuhn’s approach. While the predominance of a single paradigm may be true in the natural sciences, other scientific disciplines (e.g., the social sciences) can be labeled as multi-paradigmatic. Also, there are examples of significant scientific progress without paradigmatic crises. Progress in particle physics in the last five decades or so, for example, has led to the refinement of the “particle zoo” metaphor and the development of a standard model without sparking paradigmatic shift. In other disciplines, particularly in most social sciences, ruling paradigms hardly ever exist. In those fields of inquiry, competing (or complementary) theories often coexist. From the perspective of Kuhn’s approach, they have to be labeled as “constantly revolutionary sciences” (which would miss much of the day-to-day activities of researchers in these disciplines) or deny their status as scientific disciplines altogether. In order to explain the continuous and incremental growth of scientific knowledge, which can be found in natural and social sciences alike, Popper suggested a model of scientific *evolution* rather than revolution. In line with his fundamental principle of falsification (discussed earlier in this entry), his evolutionary approach of scientific developments starts with a particular problem (P_1). The questions linked to the problem give rise to a tentative theory (TT), which is tested and modified by what he called error elimination (EE). The process of error elimination is more than the optimization of a tentative theory but may in turn lead to the appearance of new, unexpected problems (P_2). Here the process starts all over again. The evolution of scientific knowledge can be expressed as follows:

$$P_1 \rightarrow TT_1 \rightarrow EE_1 \rightarrow P_2 \dots$$

The discovery of P_2 itself indicates an increase of knowledge. In contrast to Kuhn, Popper's model does not distinguish between distinct periods of scientific process but assumes an incremental change. Another influential model for explaining scientific progress was developed by the Hungarian-born mathematician and philosopher of science Imre Lakatos. His approach is situated between the poles of Kuhn's revolutionary and Popper's evolutionary model. For Lakatos, science is dominated neither by monolithic paradigms nor by isolated, tentative theories. Instead science is organized around *research programs*. A research program is a general/super-theory or a sequence of theories. They consist of three elements:

1. A set of *fundamental assumptions*. These form the hard core, or *negative heuristics*, of a research program, for they cannot be abandoned without rejecting the research program altogether.
2. *Positive heuristics*. These consist of a set of beliefs linked to the core assumptions of a research program but also include suggestions or hints for how to deal with potentially refuting observational evidence. In Lakatos's words, they form a "protective belt" surrounding the hard core of the research program. The hard core of the "Copernican research program" mentioned earlier is the assumption that Earth and the other planets orbit a stationary sun, forming a solar system. However, to explain and calculate the movements of the planets, supplementary assumptions (e.g., the introduction of epicycles) are necessary. Inadequacies between the assumptions articulated in the research program and actual observation can be attributed to the positive heuristics.
3. The third element of a research program is a *series of theories* ($T_1 \dots T_n$). These theories are its specific instantiations and are developed by adding auxiliary clauses to previous theories. In contrast to Popper's paradigm, Lakatos argues in favor of a more incremental form of scientific change. Research programs can be either progressive or degenerative. If the addition of auxiliary hypotheses helps to enhance the explanatory or predictive power of a research program, it is *progressive*. The hard core of its

fundamental assumptions remains well protected by its protective belt, which allows the formulation of credible auxiliary hypotheses. When auxiliary hypotheses must be added to conceal more fundamental flaws or simply to provide some answers when faced with troublesome new evidence, Lakatos speaks of *degenerative* research programs. Its incapability to provide "good" explanations on the basis of its positive heuristics may eventually lead to the erosion of some core assumptions, which can mean the "fading out" of a particular research program. In sum, Lakatos argues for an evolutionary model of scientific progress. In his view, change in research programs takes place at their respective peripheries. In the process of scientific progress, auxiliary hypotheses can lead to an overall degeneration of the program, eventually leading to the weakening of its positive heuristics. Parallel to Kuhn's conception of research paradigms, the "hard core" of a research program remains stable until the program as a whole fades out and is replaced by more productive, progressive ones.

It is against this static view of the positive heuristics of research programs, but also because of Lakatos's (as well as Kuhn's) emphasis on empirical problems as the driving force behind scientific growth, that the American-born philosopher Larry Laudan developed his own concept of research traditions. While he agrees that ultimate aim of science is the development of theories with high problem-solving capacities, his model differs from those of his predecessors in some major ways: He is fundamentally skeptical toward the belief that theories can deliver accurate insights about the way the world actually is. He attempts to circumvent the problem of the truthfulness of a theory by focusing on its problem-solving capacity. According to Laudan, unlike Kuhn and Lakatos, the quality of a theory is not solely dependent on its ability to solve empirical problems. He suggests a taxonomy that distinguishes between empirical problems on the one hand and conceptual problems on the other. Empirical problems can be further differentiated as solved, unsolved, and anomalous problems. By solved problems he refers to empirical questions adequately solved by an existing theory. Unsolved problems lack resolution by any

existing theory, while anomalous problems have been solved by a particular theory but cannot be explained by one or more rival theories. As part of the conventional wisdom, unsolved problems are regarded as the major stimulus for scientific progress. Finding a solution where none has existed drives the development of new theoretical approaches. Conceptualizing scientific progress as filling the white spaces on the map of knowledge by solving more and more problems is, in Laudan's view, too short-sighted. Likewise, changing the paradigm or adding auxiliary hypotheses to deal with unexpected (unsolved) problems falls short of explaining the nature of scientific growth. Focusing on the problem-solving capacity of theories with regard to empirical problems neglects the second category, which entails conceptual problems. Conceptual problems arise when a theory (t_1) is in conflict with another theory (t_2), which is believed to be rational and well-founded. The simplest form of conflict between theoretical concepts is their logical inconsistency or incompatibility. If t_1 entails the negation of (crucial parts of) t_2 it speaks of inconsistency, whereas in the case that t_1 employs a model of explanation that entails nothing about t_2 , the two concepts are regarded as incompatible. Apart from such intrascientific difficulties, conceptual problems can result from normative difficulties (including methodological rules as norms of good scientific behavior) or contradictions to nonscientific beliefs or metaphysical assumptions (worldviews). Laudan's term of research traditions aims at providing a criterion for theory selection given the conceptual and empirical problems outlined above. He describes research traditions as guidelines for the development of specific theories, a specific set of beliefs about the kinds of entities and processes that constitute the domain of inquiry. Additionally, research traditions entail one or more epistemic and methodological norms, which define how a specific field of inquiry must be investigated and which methods are considered legitimate.

Scientific progress, especially the deviation from existing theories and models, is, in Laudan's view, not exclusively triggered by the shortcomings of providing answers to empirical questions. Instead, even empirically well-supported theories can be abandoned in favor of less supported approaches, provided that these are equipped to

resolve conceptual difficulties confronting their predecessors.

The concept of research tradition shares a common assumption with the models of research programs and scientific revolution, namely the conviction that at any given time, a (more or less) defined set of theoretical and epistemic assumptions exists and that "good reasons" (unsolved empirical and/or conceptual problems) are necessary for abandoning theoretical concepts.

A radically contradicting view was introduced by the philosopher of science Paul Feyerabend (1924–1994). In his controversial book, *Against Method*, he argued for epistemological anarchy, a position famously culminating in his principle of "anything goes." From this perspective, scientific progress cannot be produced by methodological monism. He intended to show that compliance with the principles of methodological monism (interdiction of ad hoc hypotheses, increase of empirical content, theoretical consistency) and in particular the principle of falsification imply the impossibility of scientific progress. The principle of "anything goes" does not call for the inclusion of antiscientific methods in scientific reasoning and is no methodological principle itself, but argues against methodological rigidity and a close relation between theoretical and methodological purity and scientific progress. From this perspective, the advancement of scientific knowledge depends on a variety of factors including chance and the breaking of scientific rules, as well as non-scientific aspects (such as aesthetic criteria and social factors).

Natural and Social Sciences

So far, no distinction has been made between natural and social sciences. According to the thesis of the unity of science, all scientific disciplines are part of the same holistic endeavor to gather scientific knowledge: Common scientific laws form the basis of any scientific inquiry. However, the nature of the field of inquiry of social sciences poses some important problems for that thesis and the philosophy of sciences in general.

A longstanding question is therefore if, and to what degree, social sciences resemble natural sciences. The 19th-century French philosopher Auguste Comte imagined the emergence of

“positive” social sciences, which should develop in the image of the natural sciences. Like any other discipline, the social sciences in his view have to pass through three distinct stages: a *theological* phase, in which explanation of natural occurrences (e.g., weather events) and social occurrences (e.g., victories in battles, but also one’s personal fortune) are explained by the interference of personal deities. The initial stage is followed by a *metaphysical* phase, in which the personal and indirect influence of gods is replaced by abstract, impersonal concepts, which can be rationally analyzed. The final phase is called the *positive* stage, which is dominated by scientific explanation based on observation. Comte’s conviction that social sciences can become a kind of social physics occupied with uncovering “social laws” is disputed by many of today’s philosophers of science. Social sciences are seen as fundamentally different from natural sciences, mainly for two reasons: (1) the difference of explanation and understanding as major aims of scientific inquiry, and (2) the constructed nature of the social world and the responsiveness of societies and individual social actors to scientific findings.

One cardinal difference between natural and social sciences is that of their respective aims, stemming from the problem of classification and the historicity of cases. While both the French Revolution of 1789 and the Arab Spring since 2010 might be labeled as “revolutions,” the semantic similarities must not conceal the fundamental differences between the two cases. It is therefore questionable whether some “general laws of revolution” (explaining the causes and courses of any political upheaval) can be formulated at all or whether each case has to be “explained” by drawing on respective historical and cultural peculiarities. While the identification of laws aims at explaining underlying principles and mechanisms, social sciences, in the words of the classical German Sociologist Max Weber, seek to understand the characteristics of particular cases.

Moreover, unlike in natural sciences, social facts are constituted by societies themselves. Social laws are created (constructed) by social actors and therefore can (deliberately) be changed. Additionally, social actors can respond to the

findings and predictions of the social sciences. As the American sociologist Robert Merton stated, in the social world, scientific description can even prescribe the developments it claims to have discovered (self-fulfilling prophecy). Both of these problems limit the use of nomological-deductive reasoning in social sciences, for neither can universal laws simply be discovered nor is it always possible to explain the interplay between structure and agency by referring to universal social laws. Statistical probability and inductive reasoning, in general more important to social sciences, also has to be treated carefully. The statistical connection of a person’s educational background and her ability to reach a privileged position, for example, can change when some structural features of the society in question are altered (e.g., special programs for female students) but also when the assessment of the available career opportunities change (e.g., the role of women in general). Philosophy of social sciences today distinguishes between naturalist positions stating that the methods of social sciences should correspond to those of the natural sciences, and anti-naturalist positions, which emphasize the differences between understanding (predominant in the social sciences) and explanation (the main goal in natural sciences), which requires the inclusion of non-naturalistic methods (e.g., hermeneutics) of inquiry.

Value-Free Science and Scientific Authority

Feyerabend’s aforementioned critique of methodological monism in science is echoed by contemporary philosophers and sociologist of science. Since the 1970, postmodernists such as Jean-François Lyotard, proponents of the “strong program” in the sociology of knowledge and science and technology studies (STS), have emphasized the social role of science. With the increasing role of science-driven technological change and the paramount importance of scientific knowledge in modern societies, philosophy of science emphasizes the role of values *in* and *for* the authority of science. The role of norms and values in science has gained additional attention since scientific modeling and forecasting have

become ever more important. As mentioned earlier in this entry, understanding complex and consequential developments such as climate change involve the use of models. However, the need to decide which variables should be included invites the criticism that scientists “tailor” their model assumptions to derive predictions that correspond with normative, economic, or political preferences.

In addition to “cognitive” or “epistemic” values such as accuracy, simplicity, or coherence with accepted theories, proponents of STS and the strong program emphasize the role of contextual values in science. In contrast to epistemic values—which directly refer to, and can be derived from, the immanent logic of research—contextual values include political, cultural, and personal values and can thus compromise scientific objectivity and in consequence scientific authority. For if scientific knowledge is reflecting the cultural or personal norms of the researchers, the objectivity of scientific knowledge can be called into question. Science should then be regarded as a mere social practice that reflects the preferences and prejudices of the involved scientists.

Disputes about scientific objectivity and the role of contextual values for the production of scientific knowledge highlight new cleavages within the philosophy of science, which is increasingly concerned with understanding the political and social impacts of, and on, science. At the same time, the social role of philosophy of science itself changes: No longer limited to understanding the intricacy and inner workings of scientific research, contemporary philosophers of science increasingly reflect upon the integrity, efficacy, and legitimacy of science in modern societies.

PHYSICAL THEORY

Physical theory is concerned with the fundamental constituents of the universe, the forces they exert on each other, and the results produced by said forces. It is closely related to the other natural sciences and in many ways encompasses them. Chemistry, for example, deals with the interaction of atoms to form molecules, geology is largely a study of the physics of the world, and astronomy deals with the physics of outer space.

A physical theory is a model of physical events and cannot be proven from basic axioms. It differs from a mathematical theorem since physical theories model reality and are a statement of what has been observed. They can also provide predictions about new observations. There is therefore more to a physical theory than application or even invention since physical theories are involved in concept formulation. Very often, it is a mathematician who provides the clue to a physical theory—for example, Bernhard Riemann’s notion that space might be curved. This entry presents an overview of the foundations of physical theory and a history of its advances from origins in ancient Greece through the medieval and Renaissance periods to the present day. The entry concludes with a description of the problems and challenges facing contemporary physical theorists and researchers in their efforts to produce a

theory that unites the four known fundamental forces into a unified field theory.

Foundations

The advancement of science depends on the interaction between physical theories and experimental physics. Sometimes, physical theory develops mostly along the standards of mathematical rigor giving less weight to experiments and observations. For example, when developing special relativity, Albert Einstein concerned himself more with the Lorenz transformation than with the Michelson–Morley experiment that attempted to prove the theory. Another time, however, he paid much more attention to experiments, for example, when formulating the photoelectric effect whereby the existing experimental results required a theoretical formulation.

A physical theory is involved in the relationships between different kinds of measurable quantities. This is exemplified by the Greek physicist and mathematician Archimedes (c. 287–212 B.C.E.), who came to realize that the volume of an irregularly shaped object could be determined by immersing it in a liquid, and that a ship is able to float due to the displacement of its weight of water. The Ionian Greek philosopher Pythagoras (c. 570–495 B.C.E.) identified the relationship between a length of vibrating string and its effect on musical tone as well as how to work out the length of a rectangle's diagonal. Thermodynamics is a branch of physics that employs four rules. The second of these involves a quantity termed *entropy*, which is usually symbolized by the letter *S*, and is a measure of the number of specific ways in which a thermodynamic system can be arranged. The modern microscopic interpretation of entropy in statistical mechanics involves entropy providing the amount of additional information required to specify the exact physical state of a system given its thermodynamic specification. Entropy is often regarded as an indication of the randomness or disorder of a system.

Theoretical physics can take a number of approaches. Those working in theoretical particle physics, for example, might use empirical formulas to agree with experimental results and can do prior to achieving an understanding of the physics

behind them. *Modelers*, those who build models, may try to model speculative theories so they possess certain desirable features rather than basing them on experimental data, or they may apply the techniques of mathematical modeling to physics problems. Some theoretical physicists try to create approximate theories, known as *effective theories*, seeing fully developed theories as either unsolvable or overly complicated. Effective theories are essentially approximations to underlying physical theories. These include quantum field theory or a statistical mechanics model. These types of physical theories include degrees of freedom to describe physical phenomena that occur at selected length or energy scales while ignoring degrees of freedom at shorter distances (or higher energies). Effective theories serve to simplify calculations and enable physicists to address the effects of radiation and dissipation.

Others working in the area of physical theory may attempt to formalize, unify, or reinterpret existing theories or create completely new ones. Theoretical advances in physics often consist in putting aside older paradigms. Pure mathematics can sometimes provide clues about how a physical system can be modeled while others require computational investigation.

Physical theories become accepted if they make correct predictions and no (or few) incorrect predictions. *Occam's razor* is a principle that is often used as an injunction not to make more assumptions than you actually need. It's named after 13th-century philosopher William of Ockham, which states that the simpler of two theories that describe the same subject just as well is to be preferred. This is only true if two rival theories predict identical results but infer the same results. In science, however, it's more often the case that theories are distinguished less by making fewer assumptions *per se*—but rather by making different assumptions.

When attempting to develop a testable physical theory, scientists should follow the concepts defined in the scientific method. The scientific method is a set of techniques used by the scientific community to investigate natural phenomena by providing an objective framework in which to make scientific inquiry and analyze the data to reach a conclusion about that data. Modern

theoretical physics tries to bring theories together and to explain phenomena in even further attempts to understand the Universe, both from a cosmological point of view and on an elementary particle scale. When experimentation is not possible, theoretical theories can still attempt to further knowledge via the use of mathematical models.

Famous theoretical physicists include Isaac Newton, Albert Einstein (1979–1955), Max Born (1882–1970), Max Planck (1858–1947), Paul Dirac (1902–1984), Richard Feynman (1918–1988), Abdus Salam (1926–1996), Enrico Fermi (1901–1954), and Stephen Hawking (1942–2018).

Categories of Physical Theories

Physical theories can be grouped into three categories: *mainstream*, *proposed*, and *fringe* theories.

Mainstream Theories

Mainstream theories are sometimes referred to as *central theories*. They are the body of knowledge of both factual and scientific views and possess the scientific qualities of test repeatability; consistency with existing, well-established scientific theories; and experimentation. There are some mainstream theories that are generally accepted based on their effects explaining a large variety of data, while the detection and explanation and possible composition are open to debate. Examples of mainstream theories are *cosmology*, *dynamics*, *general relativity*, *quantum mechanics*, *string theory*, *thermodynamics*, and *particle cosmology*.

Proposed Theories

Proposed theories of physics are generally quite new theories that deal with the study of physics using scientific approaches, a means for determining the validity of models and new types of reasoning used to arrive a theory. However, there are some proposed theories that have been in the mix for decades and have so far eluded a way of testing and discovery. Proposed theories often include fringe theories that are undergoing the process of establishment and as yet are waiting to gain wider acceptance. Proposed theories are usually untested theories. Some examples

include *dark energy*, *Einstein–Rosen bridge*, *M-theory*, and *emergence*.

Fringe Theories

Fringe theories include new areas of scientific endeavor, those that are in the process of becoming established as well as some proposed theories. These can include speculative sciences in the fields of physics and physical theories, submitted in accordance with known evidence where a body of associated predictions has been put forward according to those theories. Some fringe theories subsequently become part of the widely accepted theories of physics. Others go on to be disproven. Certain fringe theories are forms of protoscience, while others are a form of pseudoscience. Disproving the original theory may lead to a reformulation of the theory. Examples of fringe theories include the dynamic theory of gravity, grand unification theory, luminiferous aether, steady state theory, and the theory of everything.

History of Physical Theory

The Babylonians, ancient Egyptians, and early Mesoamericans were early observers of planetary activity but failed to find an underlying system for planetary motion. The earliest known form of physical theory began more than 2,300 years ago in pre-Socratic Greece and was continued by Plato and Aristotle, some of whose ideas remained the mainstay for a millennium. The downside to Greek physics was that it discouraged experimentation, something which unfortunately held back science as a whole during that time. In the medieval era, when the first universities were being built, the acknowledged disciplines were mathematics, theology, medicine, and law. As the concepts of energy, space, matter, and causality developed, physics began to acquire the form of discipline we have today. During the Renaissance the modern-day concept of experimental science as a counterpoint to theory first emerged with Francis Bacon (1561–1626), who advocated the experimental method as the true foundation of scientific knowledge. He also worked on astronomy, optics, chemistry, and machine design. The Copernican Revolution was a landmark in the

history of physical theory when the mathematician and astronomer Nicolaus Copernicus (1473–1543) proposed a heliocentric system, in which the planets move around the sun. This caused a paradigm shift in astronomy that heralded the modern era in physical theory. This was soon followed by Johannes Kepler's (1571–1630) theory of planetary orbits based on Tycho Brahe's (1546–1601) meticulous calculations.

Galileo Galilei (1564–1642) was instrumental in the push toward modern concepts of explanation. As a physicist he was theoretically and experimentally gifted. He was able to confirm the heliocentric model by observing the phases of the planet Venus. He also discovered surface regularities on the moon using his newly developed telescope. Galileo was not just an astronomer, he also performed experiments that demonstrated that bodies of different weights fall at the same rate, overturning Aristotle's false dictums, and that their speed increases at a uniform rate with the time of the fall. His work foreshadowed the work of 17th-century physicist and mathematician Isaac Newton.

Newton, Classical Mechanics, and Fundamental Forces

At around the age of 23, Newton propounded the principles of mechanics, proposed a theory for the propagation of light, formulated the law of universal gravitation, and invented differential and integral calculus. His contributions to physical theory were enormous. He succeeded in illustrating that Kepler's laws of planetary motion and Galileo's theories involving falling bodies were in line with his own laws of motion and gravitation. He also predicted the appearance of comets and explained the effects of the moon on the tides explaining the precession of the equinoxes. Physics subsequently owed much to Newton, and in particular to the second law of motion which states that the force needed to accelerate an object is proportional to its mass times the acceleration. If the force and initial position and speed are known, subsequent positions and velocities can be worked out. The force may vary with time or position, in which case Newton's calculus needs to be applied. Newton's simple law was even more far-reaching in that it stated that each body possesses

an inherent property, its inertial mass, and it is this that influences its motion. The greater the mass the slower the change of velocity when impressed by a given force. This law has a practical aspect today, as long as the body discussed is not overly small, not overly big, and not moving very quickly. Newton's third law is expressed simply as "for every action there is an equal and opposite reaction"; that is, all forces between particles arise in oppositely directed pairs.

Newton's force of gravity was his chief contribution to the description of natural forces. The law of gravitation recognizes that all material particles and the bodies that are composed of them have a property termed *gravitational mass*. This causes any two particles to exert attractive forces on each other along the line joining them, in direct proportion to the product of the masses, and inversely proportional to the square of the distance between them. This law governs the motion of the planets around the sun, and the earth's own gravitational field. It is also strongly suspected to be involved in the possible gravitational collapse seen in the final life cycle of stars.

Nowadays, we know that there are three other fundamental forces in addition to gravity that are active in the universe:

Electromagnetism, which is manifested in the interaction between particles with an electrical charge. Charged particles at rest interact via electrostatic forces. In motion, they interact through both electrical and magnetic forces. For many years, electromagnetic forces were thought to be different from one another but in 1864 physicist James Maxwell unified them under Maxwell's Equations. In the mid-20th century, quantum electrodynamics combined electromagnetism with quantum physics. Electromagnetism is very evident in the world since it can affect things that are at a distance with a reasonable amount of force.

Weak interaction is a powerful force that acts on the scale of the atomic nucleus and causes such phenomena as beta decay. Weak interaction has been joined with electromagnetism in a sole interaction known as the *electroweak interaction*.

Strong interaction is the strongest of the forces that keeps nucleons (protons and neutrons) bound together. For example, it has the strength to bind

two protons together in a helium atom, even though the positive charges in the atom cause them to repulse each other. The strong interaction enables particles termed gluons to bind quarks together to create the initial nucleus. Gluons can also interact with other gluons giving the strong interaction a theoretically infinite distance.

Many physicists believe that all four fundamental forces belong to a single underlying force, which has yet to be discovered. In the same way as electricity, magnetism, and the weak force were conjoined in the electroweak interaction, research work continues to try to unify the fundamental forces. Current quantum mechanical thought is that the forces' particles do not directly interact but rather produce virtual particles that mediate the actual interactions. All forces apart from gravity have been incorporated in this standard model of interaction.

René Descartes' (1596–1650) analytic geometry and mechanics became incorporated into Isaac Newton's calculus and mechanics. Descartes provided the first truly modern formulation of the laws of nature and, in addition, constructed an influential theory of planetary motion. He rejected the use of substantial forms, instead favoring a mechanical approach to the explanation of natural phenomena, which entailed the interaction of small unobservable *corpuscles* of matter. One of his chief accomplishments was to discover the laws of refraction, commonly termed *Snell's law*, which pronounces that as light passes from one medium to another the sine of the angle of incidence maintains a constant ratio to the sine of the angle of refraction. His ambitious text entitled *The World* contained the blueprints for a mechanical/geometric physics and set out his vortex theory of planetary motion. In 1644, he published an exhaustive investigation into physics in the *Principles of Philosophy*, which also detailed the metaphysical underpinnings of his physical system.

Modern Physics

Joseph-Louis Lagrange, Leonhard Euler, and William Rowan Hamilton were responsible for extending the theory of classical mechanics, having picked up the thread interweaving mathematics

and physics started by Pythagoras more than two millennia before. The Lagrangian mechanics is a reformulation of classical mechanics, using the principle of least action. Joseph-Louis-Lagrange introduced this system in the late 18th century. The Lagrangian is a mathematical function summarizing the dynamics of the system. In a simple mechanical system, it is the value given by the kinetic energy of the particle less the potential energy of the particle; however, the principle can be extended to complex systems. This reformulation was an alternative response to Cartesian coordinates including the *polar*, *spherical*, and *cylindrical* coordinates that were found to be unsuitable for Newtonian mechanics. The Lagrangian has been used in Newtonian physics as a way to find the acceleration of a particle in a gravitational field. It has also been used in Einstein field equations, something that led to its being applied in electromagnetism, to curved space-time, and when describing black holes.

Some of the best conceptual achievements of the 19th and 20th centuries include the consolidation of the idea of energy by the inclusion of heat, and subsequently electricity, light, and mass. The laws of thermodynamics, in particular the introduction of a singular concept of entropy, filled in large gaps in the attempt to explain “why things happen.”

The most revolutionary and pivotal theories of modern physics are the *theory of relativity* and *quantum physics*. Newton's mechanics were integral to special relativity, and his gravity was accorded classical mechanical explanation by general relativity. The area of quantum mechanics was fundamental to the ensuing understanding of *blackbody radiation* and of unusual instances in the specific heats of solids. Eventually, this work would lead to an understanding of the internal structures of molecules and atoms.

Quantum Physics

Quantum physics represents the sum total of our knowledge about how matter and energy interact in the universe. Quantum physics, also known as *quantum mechanics* or *quantum field theory*, is a molecular study of atomic, nuclear, even tinier microscopic levels. The term *quantum*

means “how much” and refers to the discrete units of matter and energy that are predicted by and observed in quantum physics. Space and time, which we usually think of as continuous, also have the minutest possible values. The birth of quantum physics is attributed to the German physicist Max Planck (1858–1947) in his paper on blackbody radiation, published in 1900. The system was further developed by Albert Einstein, Werner Heisenberg, Erwin Schrödinger, and Niels Bohr, among others. Einstein actually had serious theoretical issues with the field and attempted over a period of many years to disprove or revise it.

Quantum physics deserves especial attention because it’s the science behind how everything works, providing a description of the nature of particles and how they interact. Light waves perform like particles, and particles act in the same way as waves. Matter can apparently travel from one spot to another without moving through the intervening space, something known as quantum tunneling. Information moves vast distances instantaneously. A key concept is that of *quantum entanglement* whereby multiple particles associate so that measuring the quantum state of a particle places constraints on measuring the others. This was first demonstrated by the EPR Paradox, and while this concept started as a ‘thought experiment’ it has since been confirmed via experiments, tests known as Bell’s Theorem.

Thought experiments are situations created in the mind that ask questions such as “suppose you are in a certain situation, assuming such and such is true—what would happen?” Thought experiments are sometimes created to investigate phenomena that cannot readily be experienced in everyday life. Some famous examples of thought experiments include Schrödinger’s Cat, and as mentioned, the EPR thought experiment. Thought experiments usually lead to real experiments designed to verify the conclusions, and therefore the assumptions of them. The EPR thought experiment was devised by Einstein and colleagues Boris Podolsky and Nathan Rosen as a critique against the Copenhagen interpretation of quantum mechanics.

Quantum optics is another branch of quantum physics that is concerned with the behavior of light or photons. The behavior of photons has a

bearing on out-coming light. Lasers are one important application originating from quantum optics.

Quantum electrodynamics, developed in the mid-20th century by Richard Feynman, Julian Schwinger, and others, studies how electrons and photons interact; *unified field theory* attempts to bring together quantum physics and Einstein’s theory of general relativity by seeking to unify the fundamental forces of physics. Unified field theories include *quantum gravity*, *string theory*, *superstring theory*, *M-theory*, *grand unified theory*, *theory of everything*, *loop quantum gravity*, and *supersymmetry*.

All these massive achievements were dependent on theoretical physics as a moving force to both suggest experiments and consolidate results. Often, the ingenious application of mathematics was a prerequisite, and in the case of Descartes and Newton, the invention of new mathematical systems. Fourier’s studies on heat conduction led to a new branch of mathematics, the infinite orthogonal series. Heat conduction is one of the three modes of heat transfer. In 1822, French physicist Joseph Fourier set out a treatise that gave a complete theory and mathematical model of heat conduction. Heat conduction involves the transfer of heat from a warmer to a colder object by direct contact. He discovered that heat flux is in proportion to the size of a temperature gradient, and his equation became known as Fourier’s law.

A Theory of Everything

One goal of modern physics is to develop a comprehensive “theory of everything,” which reconciles gravity with the other three fundamental forces. If this could be developed, it would have to define the tentative boundary between Einstein’s theory of relativity and quantum theory, so this “theory of everything” is referred to as *quantum gravity*.

Quantum gravity is the overall term for physical theories that try to unify gravity with the other fundamental forces of physics, which are already united. It generally supposes the existence of a theoretical entity—a graviton or virtual particle that mediates the gravitational force. The

traditional model of quantum physics developed in the early 1970s propounds that the three other fundamental forces of physics are reconciled by *virtual bosons*. Bosons are types of particles that act according to the Bose–Einstein statistics. They possess a quantum spin and are sometimes known as *force particles* since they control the interaction of physical forces. The name *boson* originates with the Indian mathematician Satyendra Nath Bose (1894–1974), who worked with Einstein early in the 20th century.

Photons are elementary particles that are known as the *quantum* of electromagnetic food. Unlike other forms of matter, they cannot be subdivided, owing to their properties of waves—they can be refracted by a lens, interfering with other waves. Photons do not decay like other particles, and they carry no electrical charges. Photons mediate the electromagnetic force, while W and Z bosons mediate the weak nuclear force. *Gluons* (e.g., quarks) are force-mediating particles and exist in every atomic nucleus, holding it together. They mediate the strong nuclear force, which is stronger than electromagnetism and gravity by a long way. The *graviton*, being a theoretical particle with no mass and no charge, mediates the gravitational force. This theoretical particle is also believed to have spin two (spin being an intrinsic form of momentum) due to gravity's being described as having a certain kind of tensor field or mathematical framework.

Proving quantum gravity is experimentally problematic because the energy levels required to observe the postulates of the theory are unachievable in current laboratory experiments. In fact, quantum gravity has theoretical problems too. Gravitation is now explained by the theory of general relativity, which sets out different assumptions about the universe at a macroscopic level compared with the assumptions made by quantum mechanics on a macroscopic level. Within theorists' efforts to combine these, the problem of renormalization rears its head, whereby the sum of all the forces do not cancel out, resulting in an infinite value. Should quantum gravity actually exist, it is also possible that it will further our understanding of space and time, another reason why physicists continue to exert their efforts in pursuing this aim. Some

unified theories that are termed quantum gravity theories include supergravity, twistor theory, noncommutative geometry, and Euclidean quantum gravity.

Physical Theory Today

Theoretical physicist Lee Smolin suggests the five major problems in theoretical physics that are still giving physicists a perplexing time today. These are: 1. *The problem of quantum gravity*. Quantum gravity is the attempt in theoretical physics to create a theory that includes both general relativity and the standard model of particle physics. At present, these theories describe different scales of nature and attempts to explore areas where they overlap have not managed to yield any meaningful results, for example, the force of gravity (or curvature of space time) becoming infinite. This is a problem since physicists cannot visualize or want to visualize any infinities in nature.

2. *Foundational problems in quantum mechanics*. There still needs to be an understanding of the underlying physical mechanism in quantum mechanics. While there are numerous interpretations including the Copenhagen interpretation, the participatory anthropic principle, and Hugh Everett's many worlds principle, there is still disagreement about what causes the collapse of the quantum wave function. Most modern physicists working in quantum theory do not consider these questions of interpretation relevant. For many, the principle of de-coherence is the explanation, that is, interaction with the environment causes the quantum to collapse. Perhaps more significantly physicists can solve the equations, perform experiments, and practice physics without needing to resolve these types of fundamental questions.

3. *The unification of particles and forces*. Controversy still rages about whether or not the various particles and forces can be unified in a theory that can explain them all as the product of a single fundamental entity. As we have already seen, there are four fundamental forces of physics, but the standard model of particle physics includes just three (electromagnetism, strong, and weak nuclear forces). Gravity is not included in the standard model; attempting to create one theory that unites

the four forces into a unified field theory remains a goal in modern-day theoretical physics. Because the standard model of particle physics is a quantum field theory, any unification would therefore have to include gravity as a quantum field theory. This means that solving the third problem is connected with solving the first problem on this list. Additionally, the standard model of particle physics indicates a large number of particles, in fact 18 in total. Many physicists believe that a fundamental theory of nature should possess a method of uniting these particles so they can be described in more fundamental terms. String theory is perhaps one of the best defined of these approaches; it maintains that all particles are varying vibrational modes of filaments of energy or string.

4. *Problem of tuning.* A theoretical physics model is a framework that requires that certain parameters be set. In standard particle physics, the parameters consist of the 18 particles asserted by the theory, so the parameters are measurable by observation. Some physicists believe, however, that it should instead be the fundamental physical properties of the theory that determine the parameters, independent of measurement. This has motivated much enthusiasm for a unified field theory, even sparking Einstein's famous question "did God have any choice when he created the universe?" The question relates to whether the properties of the universe inherently provide the form for the universe, which begs the question whether these properties would work if the form were different. Many answer this by inclining toward the idea that there is potentially more than one universe that can be created along with a wide number of fundamental theories based on different physical parameters that could be the case.

5. *The problem of cosmological mysteries.* There are plenty of mysteries still remaining, but those that perplex physicists the most are the ones to do with *dark matter* and *dark energy*. This type of matter and energy can be detected by gravitational influences only and not by direct observation. Physicists still struggle to ascertain what they are, with some proposing alternative explanations for the gravitational influences, explanations that no longer require new forms of matter and energy.

PHYSICS, ANTIQUITY

What we call physics today did not exist as a distinct unified discipline in the ancient cultures we know about. Our discipline is concerned with energy, with matter in motion and the forces that generate that motion, and with the fundamental constituents of the world. In the West, physics develops out of what was called *natural philosophy* until the late 19th century and focuses on the study of "the workings of nature." Its development into the discipline now called *physics* drew from the studies of optics, mechanics, geometry, and astronomy. These mathematical disciplines began in Western antiquity with Hellenistic writers such as Ptolemy and Archimedes and find some important precursors in Babylonian and Mesopotamian investigators. In addition to these roots in the west, important traditions for mathematizing nature are found in India and China.

Particularly important for the development of physics is the development of astronomical theories. This entry will focus on Western antiquity and its early theorizing about the workings of the natural world and then examine some of those elements from China and India.

Explanation in Early Physical Theory

Antiquity (the time preceding the Middle Ages) is generally the time we believe people began to diligently try to understand the behavior of matter. The mystery of the universe, its structure and origin, also came into serious question at this time. People wanted to understand the form of Earth and how the Sun and Moon behaved. Several theories were proposed during antiquity, and although most of them proved to be incorrect, some of those ideas hold true today. Most theories in antiquity were stated in philosophical terms, and they were typically not verified by testing. Telescopes and time-keeping equipment were not yet available.

Before antiquity, the nature of the Earth was typically explained by the actions of the gods. However, around the first millennium B.C.E., Greek philosophers began to argue that the world could be understood as a result of natural processes. They challenged typical ideas from mythology (such as the origin of the human species, though this was the origin of biology, not physics) and proposed regular underlying processes as themselves responsible for the things we see.

Ancient Greece

The Archaic period in Greece (occurring from 700 to 480 B.C.E.), the time of the pre-Socratic philosophers, marks the first known move toward a rational understanding of nature. Thales of Miletus (7th and 6th centuries B.C.E.), a philosopher known as the *Father of Science*, refused to accept mythological, supernatural, or religious explanations for natural phenomena and instead argued that every event had a natural cause. Thales also suggested in 580 B.C.E. that water is the basic element. He experimented with magnets and the attraction to rubbed amber and formulated the first cosmologies.

Thales's theories were not upheld for long, however, as Anaximander disputed his ideas and asserted that a substance called *apeiron* was the building block of all matter—not water.

Another standout philosopher was Heraclitus, who around 500 B.C.E. asserted that change was the only basic law governing the universe and that nothing ever remains the same. He was one of the first scholars to study the role of time in the universe, one of physics' most important concepts, even today.

The ancient Greek physicist Leucippus, who lived in the first half of the 5th century B.C.E., argued against divine intervention in the universe and argued that every natural event had a natural cause. Along with his student, Democritus, he was the first physicist to develop the theory of atomism, or the idea that everything is composed of indivisible elements called *atoms*.

Aristotle

During the classical period in Greece (6th, 5th, and 4th centuries B.C.E.) in Hellenistic times, physicists such as Aristotle (384–322 B.C.E.) advanced the study of natural philosophy. Aristotle, himself a student of Plato (ca. 429–347 B.C.E.), who advanced theories about geometrical objects as the constituents of matter, believed that the observation of physical phenomena could lead to the discovery of the natural laws surrounding them. In addition to his writings on poetry, metaphysics, logic, music, theater, politics, rhetoric, zoology, biology, ethics, and government, Aristotle wrote the first work that is referred to as *physics*, which is today known as *Aristotelian physics*. Aristotle explained such concepts as gravity and motion with his theory of four elements. He believed that all matter was made up of a combination of water, earth, air and fire, and a fifth element referred to as *aether*, which occupied the superlunary realm.

Aristotle believed that these four elements have a natural place and that the fundamental basis of motion in the sublunary realm is the tendency for these elements to return to that natural place. For example, if a stone is released, it moves downward toward the center of the cosmos, its natural place; flames rise upward toward the circumference, their natural place. Aristotle's ideas became

popular for many centuries in Europe, leading to scholastic and scientific developments in the Middle Ages and until the time of Galileo Galilei and Isaac Newton.

Aristotle's importance to the development of Western physics is due especially to its focus on explanatory power and coherence informed by observation. This drive toward coherence and explanation found expression in Aristotle's commitment to four modes of causation: material (that out of which a thing is made), formal (the archetype or plan), efficient (what it is that does the doing), and final (the end for which something is done). These four causes and their interpretation puzzled but also animated natural philosophers throughout the development of modern physics. (Typically today one says that physics concerns itself only with efficient causes.)

Heavenly Bodies and the Earth as Round

As with physicists since their time, the ancient Greek natural science philosophers were also interested in heavenly bodies. Anaxagoras was the first to learn that the Moon is illuminated by another light source; the Moon itself does not emit light. He also asserted that the Moon is much closer to the earth than is the Sun. He classified the Sun as a star because he believed that stars were large, luminous, and burning rocks. Anaxagoras believed that stars are further from Earth than the Sun because their brightness is not as strong.

In early Classical Greece, the idea that the earth is round was generally understood by everyone, and around 240 B.C.E., Eratosthenes accurately estimated its circumference. In opposition to Aristotle's geocentric views, Aristarchus of Samos (a Greek citizen who lived between 310 and 230 B.C.E.) presented an argument for a heliocentric model of the solar system, which placed the Sun at the center instead of the Earth.

A follower of this heliocentric theory, Seleucus of Seleucia asserted that the Earth rotated around its own axis, which also revolved around the Sun. Though his arguments have been lost in time, Plutarch stated that he was the first person to prove the heliocentric system through reasoning.

Archimedes

Archimedes of Syracuse, a Greek mathematician in the 3rd century B.C.E., is considered by many to be the greatest mathematician of antiquity and one of the greatest mathematicians of all time. He laid the foundation of statics and hydrostatics and calculated the mathematics of the lever. He also developed an elaborate system of pulleys that allowed one to move large objects with very minimum effort. The Archimedes screw is an important part of today's hydroengineering systems, and in his time, they helped the Roman army win the First Punic War.

Archimedes did not believe the arguments of Aristotle and metaphysics, believing rather that it was impossible to separate nature and mathematics, and he proved his assertions by converting mathematic theories into practical inventions.

In his work *On Floating Bodies*, which was created around 250 B.C.E., Archimedes discovered the law of buoyancy, which is also known as *Archimedes' Principle*. In mathematics, he utilized the method of exhaustion to calculate the area underneath the arc of a parabola with the summation of an infinite series. By doing this, Archimedes was able to give a rather accurate approximation of π .

Additional work by Archimedes includes the principles of equilibrium states and centers of gravity, formulae for the volumes of surfaces of revolution, and a system for expressing very large numbers. These theories would later influence Newton, Galileo, and Islamic scholars.

Hipparchus

Hipparchus, who lived from 190 to 120 B.C.E., had a life focused on mathematics and astronomy, and he utilized advanced geometrical techniques to map the motion of the planets and the stars, with the side effect of learning that solar eclipses would occur. Hipparchus also added calculations to determine the distance of the Moon and the Sun from Earth based upon improvements he made to observation instruments of his time.

Ptolemy

Ptolemy, who lived from 90 to 168 C.E., was another early physicist and was one of the leading

scientists of his time during the Roman Empire. He crafted several scientific treatises, at least three of which continued to be important throughout later European and Islamic science. The first of his astronomical treatises was known as the *Almagest* (or “The Great Treatise” in Greek—known originally as the *Mathematical Treatise*.) The second treatise was in the field of geography, which discusses the geographic knowledge of the Greco-Roman world.

Much of the information from Ptolemy and the rest of the ancient world was subsequently lost. Even the majority of the works from the greatest thinkers was lost with time. For example, though Hipparchus wrote at least 14 books, little of his direct work has survived. Only 30 of the 150 reputed Aristotelian works still exist today, and some of them are not complete.

India and China

Outside of Greece and Rome, specifically in the territories occupied by present-day India and China, there were also huge gains being made in physics.

Kanda, a philosopher from India, was the first to systematically develop a theory of atomism around 200 B.C.E. (although it is important to note that some historians have attributed him to the earlier era of 6th-century B.C.E.). This atomic theory was further elaborated by Buddhist atomists Dignaṅga and Dharmakīrti during the 1st millennium C.E. Another Indian philosopher by the name of Pakudha Kaccaya, a 6th-century B.C.E. Indian philosopher, also produced ideas about how the atom constructed the material world. All of the aforementioned philosophers believed that elements, except for aether, were physically palpable and were composed of very small particles of matter. The smallest of these particles (which could not be subdivided any further) would be called *Parmanu*. Atoms were believed to be eternal and indestructible.

Buddhists believe that atoms were not visible by the naked eye and that they could come and vanish in an instant, while the Vaisheshika philosophers believed that an atom was only a point in space. Indian theories were bathed in philosophy and were greatly abstract—they were not as grounded in research as the Greek and Roman philosophes.

They were based on logic—not on personal experience or experimentation.

In terms of Indian astronomy, the *Aryabhatiya* of Aryabhata proposed Earth’s rotation in 499 C.E., while Nilakantha Somayaji of the Kerala schools proposed a semi-heliocentric model that looked like the Tychonic system in the 1500s—long after the Greeks and Romans. Shen Kuo (1031–1095) wrote about Ancient China and magnetism in the *Book of the Devil Valley Master*.

The Role of Mathematical Theorizing in the West

The Pythagorean theorem is a relation in Euclidean geometry among the three sides of a right triangle. The theorem states that the side opposite the right angle (called the *hypotenuse*) is equal to the sum of the other two sides. The equation is written as

$$c^2 = a^2 + b^2$$

This is called the *Pythagorean equation*. The letter *c* represents the hypotenuse, and *a* and *b* represent the lengths of the other two sides.

The theorem is named after the Greek mathematician Pythagoras, who lived from 570 B.C.E. to 495 B.C.E. He is credited through tradition with the proof of the theorem, though many have said that knowledge of it predates him. There is evidence that Babylonian mathematicians understood the idea, though there is little surviving evidence that they used it as a mathematical formula. Chinese, Indian, and Mesopotamian mathematicians have all been credited with independently discovering the theorem. Some of these scholars even provided proofs of special cases.

Pythagoras is today one of the famous (and controversial) ancient Greek philosophers. He lived his early life on the island of Samos, off the coast of modern Turkey. At the age of 40, he emigrated to what is now southern Italy, where the majority of his philosophical activity occurred. However, Pythagoras wrote nothing, and there were no writings of his ideas recorded by others. By the first century of the Common Era (C.E.), Pythagoras was represented as a semi-divine figure in a largely unhistorical fashion. He was said, at the time, to have originated all true Greek

philosophy. A number of treatises were forged in his name to support this view.

We think of Pythagoras as a master scientist and mathematician. The early literature shows that he was famous in his own day—and not for mathematics. Instead, he was known as an *expert on the fate of the soul after death*. He believed that the soul was immortal and went through a series of reincarnations. He was also known as an *expert on religious ritual*, the founder of a life that emphasize religious ritual, intense self-discipline, and dietary restrictions. In addition, he was reputed to be a wonder worker who had a thigh of gold and could be in two places at once.

Today, controversy occurs around the idea that Pythagoras engaged in the rational cosmology that is considered indicative of the pre-Socratic scientists/philosophers. It was a matter of opinion whether he was any sort of mathematician. If early evidence is to be believed, he did present a cosmos that was structured according to moral principles and significant numerical relationships, which were similar to the ideas found in Platonic myths.

In this sort of cosmos, the planets were known as *instruments of divine vengeance* (such as “the hounds of Persephone”), and the Sun and Moon are known as *where people go when they live a good life* (the “isles of the blessed”). The thunder, for its part, was representative of a threat—used to frighten the souls being punished in Tartarus, the infernal region of the underworld.

It was also believed that the heavenly bodies appeared to have moved in accordance with the mathematical ratios that govern the musical instruments and produce music from heaven known as *the harmony of the spheres*. It is not believed that Pythagoras thought in terms of spheres. There is, however, evidence that he valued relationships between numbers (as in, e.g., the Pythagorean theorem).

Pythagoras’ idea of the cosmos was developed to be more mathematical/scientific by his successors, Archytas and Philolaus. Because of his optimistic argument about the fate of souls, Pythagoras succeeded in advocating a life that was attractive to his devoted followers.

That is not to say that Pythagoras did not believe in mathematical ways of thinking. He, together with his students, attempted to explain

the world utilizing numerical relations. Plato was mentor to Aristotle, and he believed that no wisdom could exist outside of mathematical reason.

Other followers of Pythagoras developed the theory that Earth was spherical and not located in the center of the universe. This theory stated that the Moon, the Sun, and the planets, including Earth, revolved around a central fire. This fire could not be spotted by anyone on Earth, however, because of an “anti-Earth” that blocked its view.

Geometry

The mathematical science of geometry, as used to understand nature, was first employed in both astronomy and physics in the 4th century C.E., maturing by the Hellenistic and Greco-Roman period. The Pythagorean mathematical point of view of nature was upheld during this time, but as the mathematical view was coupled with the world of the senses (as in the Platonic dialogues), little sound physics could be extracted. Though thinkers such as Plato were the leading theorists of their time, many of their ideas were later disproven. The physics of Aristotle continued to remain influential for centuries, although eventually it was shown that many of his ideas were incorrect.

One area in which early Greek mathematicians excelled was geometry, or the study of classical problems in mathematics. Three major problems arose, concerning the following mathematical issues: (a) angle trisection, (b) doubling of the cube, (c) constructing a cube which has a volume double that of a given one, (d) squaring a circle, (e) trisecting an arbitrary angle, (f) constructing a regular heptagon (which is a polygon with seven sides), and (g) constructing a square that has an area equal to that of a given circle.

These problems stood out for the ancient Greeks because they did not have solutions or their solutions were extraordinarily difficult to determine. The Greeks could not find simple solutions for these problems, and they were further impeded by the fact that all known solutions violated an important condition for these kind of issues—one of which the Greek mathematicians themselves had imposed. This condition stated that all valid solutions to construction problems are composed of a finite number of steps, which

consist of only two types: drawing a circle with a given center and radius and drawing a straight line through two points with a ruler (or a straight-edge). The fact that no solution exists subject to the self-imposed constraints was proved only rather recently—in the 19th century.

Doubling the Cube

Doubling the cube is the most famous of this collection of problems, and it is often referred to as the *Delian problem*, owing to the legend that the Delians consulted Plato on the matter. Another story states that the Athenians in 430 B.C.E. consulted the oracle at Delos to try and stop the plague their country was experiencing. These Athenians were advised by Apollo to double his altar that was created in the form of a cube. The scientists tried and failed several times to satisfy the god, and they eventually had to turn to Plato for advice to avoid Apollo's wrath. According to a letter from the mathematician Eratosthenes to King Ptolemy of Egypt, Euripides mentioned the Delian problem in one of his tragedies, which is now lost.

Constructing a Regular Heptagon

Regular squares, triangles, hexagons, and pentagons are all easily constructible. Octagons, on the other hand, are constructible on the heels of squares with a single angle bisection. All polygons obtained from the above four by doubling the number of sides are also constructible. However, this does not hold true for a heptagon, a seven-sided polygon.

By the year 1796, at the age of 19, Carl Friedrich Gauss (1777–1855) showed that a regular heptadecagon (a 17-sided polygon) is constructible. He showed that this heptadecagon was only a particular case of a family of constructive regular polygons. This is to say that an n -gon is constructible whenever n is a special kind of product of terms: The first is a power of 2, the rest (and there may be none) are distinct Fermat primes (that is numbers that are prime and of the form: 1 added to 2 itself raised to the power of a power of 2). Later, the French mathematician Pierre Wantzel proved that no other type of regular polygon is constructible.

Angle Trisection

Angle trisection is another of the Greeks' famous problems, though today we believe that

there is little difficult in trisecting an angle. In the classical framework, there are two types of lines drawn: circles and straight lines. The same simple approach applies to bisecting both circular arcs and straight-line segments.

The issue of trisecting a line segment is as simple as finding its n -th part for an arbitrary n . However, the issues of trisecting an angle (such as an arbitrary angle) is not solvable in a finite number of steps. Two points must be made, the first of which is that some angles are trisectable with a compass and ruler. One example of this is the three quarters of the straight angle: 67.5° . The angle is obtained by two consecutive angle bisections and makes the angle itself constructible. The third angle is obtained along the way. Angles of 45° (bisect a right angle) and angles of 30° (draw a right triangle with a side 1 and hypotenuse 2) are both constructible. The latter also leads to a classical trisection. This leads to some difficulty, as an arbitrary angle cannot be trisected with a ruler and a compass (as the Greeks asserted that it must be).

Another example is as follows: if one considers the geometric series $1/4 + 1/16 + 1/64 + \dots$ that adds up to $1/3$, we know that that adds up to $1/3$. Once an angle is bisected, we may also find its 2 - n -th part, for any n , and one may construct $1/4$, $1/16$, $\dots$ of any angle and, in principle, find its third after an infinite number of steps. This solution is universal, but it requires an infinite number of steps, which is forbidden.

This issue was solved in 1837 by Wantzel, who proved that there was no solution for trisecting a 60° angle in the classical framework.

Squaring a Circle

All of the solutions for the impossibility proofs show that each depends on demonstrating that roots of third-degree polynomial equations are not constructible. Squaring a circle, however, sits in a completely different category. The issue was solved in the 19th century, when the number π was shown to be transcendental. It is not algebraic, and it is not constructible. However, the area of a circle with a radius of 1 is exactly π . If a square with such area were constructible, the number itself would be, as well.

All of these mathematical puzzles and the limits to thought they reveal are interwoven with the

history of attempts to mathematize nature and thereby to provide clear and coherent explanations in terms of underlying processes of the phenomena we see around us.

PHYSICS, CONTEMPORARY

Theories are conceptual frameworks that play a leading role in articulating the achievements, state, and condition of contemporary physics. An understanding what the leading theories are, how they formed, how to interpret them, and their societal contexts is essential to the study of the philosophy and history of physics. This entry traces the path of theory in physics from its early development in the 16th and 17th centuries through the classical era of Newtonian mechanics and subsequent 20th-century development of relativity and quantum theory up to present-day interpretations and emerging theories such as string theory, supersymmetry, and others.

The term *theory*, however—even in contemporary mathematical physics—is ambiguous, and can have a gamut of meanings, including speculation, hypothesis, explanation, interpretation, and solidly or fully established package. As this entry

shows, the word can apply to a range of structures, for instance to a comprehensive account of a single comprehensive area of physics, as *quantum theory*, or to a subset thereof, as quark theory. The word has still other kinds of uses; the expression “effective field theories” refers to structures that seek to model effects without modeling causes, such as in BCS theories of superconductivity (named for its formulators John Bardeen, Leon Cooper, and Robert Schrieffer). But far from being a weakness, these ambiguities are a strength, part and parcel of why theories have been and continue to be so important in physics. Some proposed theories, for instance, initially have had no experimental tests, or have even been experimentally disproven, and only later have become indispensable, without it ever being incorrect to refer to them as theories.

Several factors make a theory robust despite these many ambiguities. First, theories *frame* existing knowledge, organizing what scientists have learned, giving them a grip on what is possible and impossible at the present moment. Electromagnetic theories, for instance, systematize present-day knowledge about electric and magnetic phenomena. Second, theories *scale* such knowledge, showing how to relate what happens at one level to what happens at another, the way that electromagnetic theory allows us to relate the behavior of charged bodies to that of subatomic and astronomical phenomena. Third, theories *orient* scientists by indicating how to utilize and explore phenomena such as electromagnetism, indicating what questions need to be investigated and suggesting ways to go about investigating them. Because theories frame, scale, and orient, they possess a coherent core that is more important than more external properties such as empirical confirmation or testability. It is therefore wrong to refuse to deem something a theory simply because, say, it collides with experimental results or may be currently untestable.

One notable example of a theory that contradicted existing knowledge is Yang–Mills theory, a mathematical scheme published in 1954 by Chen Ning Yang and Robert Mills, as a possible tool for describing the strong interaction in elementary particle physics. It was in direct conflict with at least one critical element of what was known

about particle physics at the time. In existing particle physics theory force-carrying particles had to be massive, while in the proposed Yang–Mills theory, they were massless. The authors published their theory anyway. Two decades later, the modification of other elements in particle physics theory made it not only possible but necessary to incorporate Yang–Mills theory into particle physics, and today, Yang–Mills is one of its core structures.

Another example is string theory, in which elementary particles are not viewed not as points but as one-dimensional strings. It makes no predictions that are experimentally testable now or that will be in the immediate future, and for this reason, some physicists have denounced it—albeit caustically—as having a similar epistemological status as astrology, intelligent design, and other forms of pseudoscience. Nevertheless, many theoretical physicists not only work in string theory but also consider it one of the most promising approaches in physics, as potentially reconciling relativity and quantum mechanics.

Historical Origins

The roots of contemporary theories of physics began to develop in the late 16th and early 17th centuries and sprang from the confluence of at least three key historical and cultural developments in particular.

One of these was the way that nature came to be seen as occupying its own realm, separate from that of the spiritual. According to early Catholic doctrine, nature was Creation, and to be understood as the product of divine activity, and not therefore to be completely distinguished from scriptural writings and the divine mind. “The heavens declare the glory of God,” reports Psalm 19 in the *Bible*, “and the firmament sheweth his handywork.” One traditional way that early theologians expressed this was to say that God wrote two books, the Book of Scripture and the Book of Nature, which had to be read together as they shed light on each other. By the 16th century, however, several historical developments made it seem as if these two books had no connection and had to be read separately. These developments included numerous voyages of adventure in which explorers turned up things not discussed in the Bible, and

the Protestant theological insistence that the Bible can and must be read by individuals relying on its words alone.

How, then, *did* one read the Book of Nature? The second key development was that the syntax of this book was mathematical. This development is identified most closely with Galileo Galilei, who argued—rhetorically, at least in part—that the Book of Nature was written in mathematical figures, and that thus only those who understood mathematics were able to read it. Still, a third intersecting development was the growing influence of theory-making, or the belief that true knowledge required stepping back and viewing what is to be known from a distance, as if one were looking at those things on the other side of a glass plate.

Classical Theories

These three developments form the background for the development of classical mechanics in the 17th century. The foundation of classical mechanics is provided by Isaac Newton’s 1687 book *Philosophiae Naturalis Principia Mathematica*, known simply as the *Principia*, whose definitions, axioms, and proofs outlined a theory of the laws of motion and of universal gravitation. Classical mechanical theory is based on several assumptions. One is that of homogeneity: space, time, and laws apply across all scales, from the atomic to the cosmic. Another is that of *simple location*, or that things to which it applies have distinct identities and are always located at a particular place at a particular time. Yet other assumptions are that the movements of these things are deterministic and predictable and due only to mechanical pushes and pulls without requiring to be explained with reference to human thought and actions.

In Newtonian theory, the world is conceived as akin to a fishbowl that contains only bodies, the only thing these bodies do is move, and the only things that make them move are forces—and that we peer into this world from the outside. The world to which classical mechanical theory applies is a mechanical, mathematical, and thoroughly comprehensible, in which all objects—grains of sand, chandeliers, swings, cannonballs, dancers, planets, and galaxies—are treated as objects moving under the influence of forces, and whose

motions therefore can be calculated and predicted. Newtonian theory therefore promised that the world was fully intelligible, and it considerably broadened the ability of humans to dominate and control it. Its success at this has tempted some philosophers into instrumentalism, or the view that the purpose of theories is to dominate and control nature.

Historians of science run the gamut from pure externalists, who approach all developments in science—including theories—as social products, to internalists, for whom theories are to be viewed as arising in the lab from scientists motivated by data. An extreme externalist was the Marxist Boris Hessen, who in his 1931 article “The Social and Economic Roots of Newton’s *Principia*” treated classical mechanics as principally the successful product of bourgeois members of industrialized society who were seeking to dominate nature and control the working classes through improvements in the modes of production and in weaponry. *Internalist* scholars, however, have attacked the *Hessen thesis*, arguing much more plausibly that Newton’s work arose principally from his understanding of predecessors and his desire for coherence and universality.

The laws, principles, and axioms of classical theory had a huge social impact in areas as diverse as education, religion, literature, political theory, and philosophy. It inspired early socialists as well as Karl Marx to seek deterministic and universal laws, and it inspired the framers of the U.S. Constitution as well. By seeming to outline criteria of objectivity, classical Newtonian theory also strongly influenced numerous philosophers, including David Hume and Immanuel Kant. So strong was its social impact that Newtonian theory has been described as the foundation of modernity. Newtonian theory persisted for over 300 years with its basic outlook virtually intact. New phenomena, concepts, and theories appeared—such as interference, wave phenomena, and the Maxwellian theory of electromagnetism—but nearly all of their elements were incorporated into classical mechanical theory.

Then came two bombshells at the beginning of the 20th century, relativity and quantum mechanics, which exposed elements of classical theory as mere assumptions, and which required new kinds

of theories and whose scientific and social effects were extensive. For all their considerable differences, both relativity theory and quantum theory coincidentally developed in two phases, with the first phase of each having minor, and the second major, scientific and social impact.

Relativity

Unlike quantum mechanics, the development of relativity theory in each phase came about almost completely through the efforts of a single person, Albert Einstein. Its first phase, known as *special relativity*, was the product, in brief, of Einstein’s attempt to resolve one of the few inconsistencies that arose between two previous theoretical systems, Newton’s and that of the 19th-century Scottish mathematician James Clerk Maxwell. At the core of classical Newtonian mechanics is the relativity of motion, meaning that the laws of physics stay the same in any inertial reference frame, or a reference frame moving at constant speed. The same laws of physics, that is, describe billiard balls, falling objects, and the movements of dancers on the ground—and on a smoothly moving train or on any platform moving constantly and linearly at any speed. In an inertial reference frame, that is, no experiment could be carried out to determine whether or not it was in motion. The equations used to connect motions in two different inertial reference frames are called *Galilean transformations*. But according to Maxwell’s theory of electromagnetism, light moves at constant speed regardless of reference frame. Light was assumed to have this property because it was assumed, like sound, to move in a medium that fixed its motion, a medium called *ether*. If light did, however, it should travel at different speeds when moving in different directions. In experiments conducted in 1881 and 1887, the physicists Albert Michelson and Edward Morley failed to detect such a difference; light indeed seemed to travel at the same speed regardless of inertial frame. The special theory of relativity, which Einstein proposed in a 1905 paper, was the product of an attempt to develop sets of equations, known as *Lorentz transformations* (named after the Dutch physicist Hendrik Lorentz), to reconcile the theories of Newton and Maxwell, without invoking effects of the ether, by giving the compensations of space and time needed

to preserve the constancy of the speed of light in different inertial frames of reference. In another 1905 paper, Einstein drew out a dramatic consequence—that the mass of a body is related to the energy it contains, by the famous formula $E = mc^2$, plus a less famous corrective factor (omitted in popular presentations) related to the body's motion.

Whereas the theory of special relativity arose from preserving invariance in inertial reference frames, general relativity arose from preserving invariance in accelerated reference frames. Einstein proposed, for instance, that no experiment could determine whether one were inside an elevator car accelerated by forces (or floating in empty space) or at rest in a gravitational field (or freely falling in one). He now sought another set of equations to describe what happens in an accelerated frame of reference. The implications of this set of equations, called *general relativity*, has profound consequences for space and time, and makes the general theory of relativity radically different from classical theory and even special relativity. Space and time are linked, general relativity implies, and the resulting space-time is curved by the mass in it. Space-time tells mass how to move, in a famous formulation, and mass tells space-time how to curve. This theory also requires a fourth-dimensional surface to represent the gravitational field.

Revolutionary new scientific theories rarely spring solely from laboratory work, and several scholars have proposed that certain social influences may have played a contributing role to the development of relativity theory—that the pressing problem in Europe at the beginning of the 20th century of coordinating time in order to make trains arrive, depart, and run on schedule helped inspire special relativity, and that the growing awareness of curved spaces in non-Euclidean geometry and of fourth-dimensional space were at work in the development of both relativity and modern art.

General relativity had a strong impact on philosophy, principally via its implication that the shape of space is not inherently Euclidean, as nearly all philosophers, including Kant, had assumed; Kant, in fact, had claimed that the *form* of human sensibility was transcendental—non-empirical—and necessarily Euclidean. But according to the theory of general relativity, the shape of space was not intuitive but to be empirically determined. This hardened a rift between two groups

of philosophers: logical empiricists, who saw the theory of general relativity as refuting Kant and as indicating that sensibility and the understanding were split, and transcendental philosophers, who saw general relativity as mandating a revision of the necessary link that Kant saw between sensibility and the understanding.

Quantum Mechanics

In 1900, Max Planck proposed what is now known as the Planck energy formula, $\epsilon = nh\nu$. One of the most fundamental equations expressing the structure of the world, it says that the energy (in Planck's initial case, of resonators of a certain frequency) could not have any energy value, as classical physics implied, but only values separated by an integer multiple n of $h\nu$, ν being the frequency, and h being what has come to be known as Planck's constant, a measure of the smallest quantum of energy. Planck knew that what he was doing was inconsistent with classical theory, and introduced it as a stop-gap measure, on the assumption that his proposal could be eventually reconciled with classical theory. He did not imagine that the idea, introduced to explain puzzling experimental results, would revolutionize physics theory in a way that would eventually replace classical theory.

During the quarter century that followed, however, new developments inserted the quantum ever more fundamentally into physics theories: Niels Bohr introduced it into the structure of the atom in 1913–1914, Einstein used it in papers of 1916–1917 that put probability into the foundations of atomic theory, and it was an element of Wolfgang Pauli's exclusion principle, proposed at the beginning of 1925. During this quarter-century, however, quantum theory remained essentially a collection of amendments to classical theory; quantum theory, so to speak, was like having only a set of instructions for getting from one place to another when what one really needed was a map of the entire terrain. Meanwhile, the public viewed quantum theory as akin to relativity in that, however important and fundamental, it was unintelligible to the layperson. Quantum theory therefore had very little cultural impact, though it did introduce a few terms into public vocabulary. One was *quantum leap*, which in an age of typewriters and

telegraphs was warmly embraced to refer to tiny discontinuous transitions but has since come to refer to gigantic transitions.

Then, in one of the most startling and far-reaching episodes in the history of science, in the short space of the 2 years 1925–1927, not one but two such maps appeared. One was created by Werner Heisenberg, who had assumed that what was blocking physicists from developing a full theory of the quantum world was their assumption that its events were picturable (*anschaulich*), when in fact quantum phenomena were unpicturable, *unanschaulich*. Quantum phenomena, he proposed, could be described only by a special form of mechanics, called *matrix mechanics*, in which certain properties were not commutable. The second map, created by Erwin Schrödinger, was based on the much more picturable wave theory, but whose waves were about the *probabilities* of events. Although sharply different, the two maps were soon shown to be essentially identical, in what became known as *quantum mechanics*.

The newly mapped territory was much different from Newton's. It was marked by inhomogeneity, or differences across scales, applied to the quantum and to the classical worlds. It also included violations of *simple location*, for it included *entangled* phenomena, whereby where states are linked despite being physically far apart—unheard of and impossible in the classical world. Some of its events were also unpredictable and uncertain, for certain properties could not be pinned down or even said to *exist*. Finally, however humans measure quantum phenomena, these phenomena cannot be viewed as if through a pane of glass but the act of measuring changes key properties of the phenomena being measured.

Quantum mechanics had a huge impact on human thought, one major example being the multiple philosophical and metaphorical valences attributed to Heisenberg's *uncertainty principle*. The uncertainty referred to is, in philosophical vocabulary, not just epistemological, or having to do with what we *know* about nature, but *ontological*, or having to do with nature itself. It refers not to information that investigators don't happen to know, but to information that in certain circumstances investigators *cannot* know. Quantum mechanics has had an impact on other fields. Within two years of the introduction of the

uncertainty principle, for instance, the philosopher John Dewey cited it as a confirmation of his spectator theory of knowledge. Quantum mechanics has contributed widely used images and terms in popular culture, such as complementarity, Schrödinger's cat, and alternate worlds.

Externalist historians and sociologists have occasionally attempted to account for quantum mechanics as a social product, with the most notorious of these the *Forman thesis*. In his 1971 article "Weimar Culture, Causality and Quantum Theory, 1918–1927: Adaptation by German Physicists and Mathematicians to a Hostile Intellectual Environment"—which is one of the most influential and controversial article in the historical studies of science—the historian of science Paul Forman argued that the founders of quantum mechanics were motivated to compose the acausal and probabilistic theory of quantum mechanics because of the anxiety of the post-World War I intellectual climate, which rebelled against rationalism and causality. As Forman saw it, quantum mechanics belonged to the same intellectual atmosphere that produced Oswald Spengler's influential 1918 book *The Decline of the West*. Internalists, however, have pointed out problems in the article, including its sources, which are mainly popular speeches rather than laboratory notebooks, as well as the fact that Einstein's introduction of probability into the foundations of the theory preceded Forman's start date of 1918.

Interpreting Quantum Mechanics

Although quantum mechanics is a complete, exhaustive, and thoroughly tested theory, its interpretation—how its terms and structures connect with the rest of human knowledge and experience—is one of humanity's great intellectual challenges. Its various interpretations have such radically different implications for the structure and character of the world that they are also themselves often called *theories*.

Copenhagen Interpretation

The first and most widely known interpretation of quantum mechanics, the *Copenhagen Interpretation*, was crafted by Niels Bohr and Werner Heisenberg in the late 1920s and early

1930s. It was named after Bohr's birthplace, as well as the site of his Institute of Theoretical Physics, where much of the theory was worked out. The Copenhagen Interpretation presents the world as the product of two ingredients. The first is an information function, the ψ -function described by Schrödinger's equation, which is a classical wave that expands outward and overlaps, or *superposes*, numerous possibilities. The second ingredient is a measurement or some other interaction with the classical world that evaporates or *collapses* the function, making one hitherto only probable state become *real* and eliminating the others. According to this interpretation, all we can ultimately know of the world prior to acts of observation or measurement is a set of probabilities, specified by the ψ -function, for which states might be realized. The Copenhagen Interpretation in effect divides the world into two entirely separate domains: the quantum world governed by the unobservable and intangible ψ -field and the deterministic classical world. As Bohr saw it, the Copenhagen interpretation was an effectively modified Kantianism: We must use classical language to describe as best as we can something to which classical language does not apply. The Copenhagen Interpretation challenged conventional notions so directly and deeply that it sparked a kind of philosophical opposition, even among scientists themselves.

Hidden Variables

One way to eliminate the division between the classical and quantum worlds is to deny the fundamental character of the first ingredient mentioned earlier, the wave function. This path was promoted most notably and persistently by Einstein, who insisted that quantum states don't represent real states of affairs but only states of our knowledge. In this interpretation, there is no true information wave function, no superposition, and no intrinsic probability of states appearing; quantum mechanics is simply incomplete. More factors exist than we have discovered, and more thought and inquiry will surely discover these and restore causality, determinism, picturability, and the other key features of the Newtonian world. Versions of the hidden variable theory

appeared at the very beginning of quantum mechanics, and have persisted to this day. But as all the predictions of quantum mechanics, even the strangest, have passed experimental tests, this theory survives on a promissory note.

Alternate Worlds

Another approach that rejects the Copenhagen interpretation denies the second ingredient mentioned above, the collapse of the wave function. Measurement and other contact with the classical world does not, and cannot, eliminate the other possibilities, which continue to exist, branching off from each other. Introduced in the 1950s, this interpretation also still has advocates. In restoring consistency and coherence to the theory, however, it does so by muddling the concept of reality.

QBism

Still another interpretation is known as *Quantum Bayesianism*, now QBism. Like Einstein, it says quantum states don't represent real states of affairs but only states of our knowledge; unlike Einstein, it embraces this, saying that this indicates not the incompleteness of quantum mechanics but that the probabilities derived from a quantum state are subjective, *Bayesian* probabilities, degrees of belief or uncertainty in a subject. In the context of quantum mechanics, QBism sees probabilities such as those of the Born rule (which gives the probability that a measurement of a quantum system will yield a given result) as normative rather than prescriptive, a guide for making judgments about quantum events. This interpretation eliminates many paradoxes. The *collapse* of the wave function simply updates the subject's beliefs. Entanglement disappears because the correlations are not simultaneously experienced. Because QBism starts from the experience of the subject, the approach bears certain affiliations with phenomenology.

But these are only a few interpretations of quantum mechanics; other, more technical interpretations include operationalism, decoherence theory, and the consistent-histories interpretation. Another set of theories ambitiously attempts to incorporate relativity theory and quantum mechanics; besides

string theory, these include M-theory, supersymmetry, supergravity, loop quantum gravity, relational quantum mechanics, and others.

Theory and Practice

Theories exist throughout branches of physics, often as a blend of quantum and classical theories. Sometimes, they exert more of an impact than others. The theory of defects, for instance, played a major disciplinary role in bringing together the physics of specific materials—metals, ceramics, glass, and so forth—into a single field, materials science.

Whereas theories play a leading role in articulating the achievements of contemporary physics, they may play less of a significant role in its practice. For in the laboratory environment, physics does not unfold abstractly independently of artifacts, tools, and practices, and it is therefore not free of instrumental mediation. Such forms of mediation are not just artifactual but also include analogies, images, and calculational tools including what Ursula Klein calls *paper tools*, which can shape the projects that theorists undertake and even imagine doing. The influence of these mediating influences may call into question the primacy of the role theories play in the practice of theorists.

PHYSICS, ENLIGHTENMENT

The Age of Enlightenment, which historians generally date from the mid-17th century through the 18th century, is a period in the history of Western thought and culture characterized by dramatic changes in philosophy, science, politics, and the social order. Increasing dissatisfaction with the medieval worldview and its domination by religious dogma and hereditary monarchies had already resulted in widespread political dissent, the Protestant Reformation, and decades of often violent conflict between adherents of the old order and militant reformers.

Among the great upheavals of the 18th century was the French Revolution, which followed in the wake of the successful American War of Independence against England, and in which the political power of the Catholic Church and the social orders of the French nobility and monarchy were called into question and then violently dismantled in the name of liberty and equality for all—ideals that both American and French reformers

claimed were founded upon the principles of human reason.

Ideas which were dismissed with the Enlightenment include many of the presuppositions that had long guided, and constrained, philosophical inquiry. Philosophy now gained the status of an independent force with the power to challenge old beliefs and construct new ones in the realms of both practice and theory, on the basis of its own principles. The revolution in science began when natural philosophers mounted an attack on the medieval Scholastic philosophical program and began to integrate concepts such as mechanics and astronomy, eventually leading to a universally valid characterization of motion and various other concepts.

The new branch of science was used to explain the natural world by accounting for a wide variety of phenomena with a relatively small number of mathematical formulae. The philosopher, mathematician, physicist, and music theorist Jean le Rond D'Alembert (1717–1783) was a leading figure of the French Enlightenment, and he wrote of it as the century of philosophy *par excellence* because of the incredible intellectual progress of the age, the enthusiasm of that progress, and the advances of the sciences. There was an idea that philosophy would improve overall human life.

During the 16th and 17th centuries, considerable scientific progress was made throughout Europe. The revolution in science began when natural philosophers created an attack on the Scholastic philosophical program and began to integrate concepts such as mechanics and astronomy, which led to a universally valid characterization of motion and various other concepts. Beginning in the 18th century, the mechanics first presented by Isaac Newton were developed by several mathematicians as they learned calculus, and its initial formulation was elaborated upon. Mathematical analyses were performed and applied to problems of motion. This was known as *mixed mathematics* (or rational mechanics) and was later called *classical mechanics*.

The following sections discuss important developments in the field of physics, among which are the predicted periodicity of Halley's comet by Edmond Halley in 1705; Benjamin Franklin's assertion in 1752 that lightning is electricity; the proposal of the electrical inverse-square law in 1767 by

Joseph Priestley; William Herschel's discovery of the planet Uranus in 1781; John Michell's assertion in 1783 that some objects are so massive that not even light could escape from them; the introduction of the inverse-square law of electrostatics in 1785 by Charles Coulomb; Henry Cavendish's measurement of the gravitation constant (which led to the determination of the mass of Earth) in 1798; and Count Rumford's idea that heat was a form of energy, which he proposed in 1798.

Physics, as Demonstrated Through Mechanics

During the Enlightenment, rational mechanics revolved primarily around the development of elaborate mathematical treatments of observed motions. These mechanics used Newtonian principles as a basis and emphasized improving the tractability of complex calculations, as well as developing a working means of analytical approximation. A textbook on these matters was published by the Hungarian professor of physics and philosophy Johann Baptiste Horvath (1732–1799) during this time, and by the end of the century, scholars had developed analytical treatments that were strong enough to verify the stability of the solar system based only on Newton's laws—divine intervention had no place in these theories. However, deterministic treatments of the three-body problem in gravitation and other simple issues remained intractable.

Significant Contributors

Among the Enlightenment's illustrious thinkers are Colin Maclaurin, who discovered uniformly rotating self-gravitating spheroid in 1742 and Leonhard Euler, who solved the ordinary differential equation for a forced harmonic oscillator, along with the phenomenon of resonance in 1739. However, British work, performed by mathematicians such as Maclaurin and Taylor, fell behind Continental developments, where academics were succeeding as led by mathematicians such as Euler, Pierre-Simon Laplace, Daniel Bernoulli, Joseph-Louis Lagrange, and Adrien-Marie Legendre.

In 1743, d'Alembert published his work *Traité de Dynamique*. Within this text, d'Alembert introduces the idea of generalized forces that can

accelerate systems and systems within constraints. Three years later, Pierre Louis Maupertuis applied minimum principles to mechanics. Shortly after, in 1759, Euler solved the partial differential equation of the vibration of a rectangular drum. He then found the Bessel function solutions for the differential equation for the vibration of a circular drum.

Other key thinkers include John Smeaton, who in 1776 published a paper on experiments that connected kinetic energy, work, momentum power and supporting the conservation of energy, and LAGRANGE, who presented his equations of motion in *Mécanique Analytique* in 1788.

In 1789, Antoine Lavoisier stated the law of conservation of mass. Newton's mechanics were discussed in both the *Celestial Mechanics* (1799–1825) of Laplace and Lagrange's 1788 work.

In 1733, the fundamental frequency of a stretched vibrating string (in terms of tension and mass per unit length) by solving a differential equation was derived by Brook Taylor. Following on this study, Swiss mathematician Daniel Bernoulli (1700–1782) studied and made discoveries concerning the behavior of gases, which anticipated the kinetic theory of gases proposed more than a century later. Bernoulli has often been called the *first mathematical physicist*. In 1734, 1 year after harnessing the power of the differential equation, Bernoulli solved the differential equation for the vibrations of an elastic bar clamped on one end. His examination of fluid dynamics and research of fluid flow were outlined in his work *Hydrodynamica*, published in 1738.

Thermodynamics

The field of thermodynamics was developed during the 18th century through the theories of weightless *imponderable fluids*. These included electricity, heat (*caloric*), and phlogiston (which was discarded as a concept when oxygen gas was identified late in the century). These fluids, as assumed real fluids, could be traced by their flow through chemical reactions or a mechanical apparatus.

Experiments in thermodynamics led to the creation of new types of experimental apparatus, such as the Leyden jar, invented in 1745 and used for storing static electricity. New types of measuring instruments were developed as well, including

the calorimeter. Improved versions of existing tools, such as the thermometer, were also developed, along with new concepts, such as Joseph Black's idea of latent heat and Benjamin Franklin's argument that electrical fluid flows between places of deficit and excess (later referred to as *positive* and *negative charges*). Franklin is most well known, however, for his discovery in 1752 that lightning is a form of electricity.

In the 18th century, as mentioned above, heat was viewed as a type of fluid, called *caloric*. This theory was later shown to be incorrect, but scientists of the time working under this assumption were able to make several important discoveries. These scientists included Henry Cavendish and Joseph Black. This theory of heat was opposed to the theory of heat that arose during Newton's time, which stated that heat is a product of the motions of the particles of a substance. This theory gained support in 1798 due to the experiments of Count Rumford (also known as *Benjamin Thompson*), who found a direct relationship between mechanical energy and heat.

Although scientists in the 18th century knew that finding absolute theories of electrostatic and magnetic force (much like Newton's principles of motion) would be an incredible achievement, none were easily found. However, as additional experimental practices became widespread and refined in the early years of the 19th century and analytical methods of rational mechanics were applied to experimental phenomena, especially with Joseph Fourier's analytical treatment of the flow of heat, a solution began to emerge. In 1767, the English polymath Joseph Priestley proposed an electrical inverse-square law, and, in 1798, Charles-Augustin de Coulomb introduced the inverse-square law of electrostatics. (Both Priestley and Coulomb are discussed later in this entry.)

By the end of the 18th century, the members of the French Academy of Science were clearly leaders in the field of mechanics; however, the traditions established by Galileo Galilei and his followers continued to exist. Along with the French Academy of Science, the Royal Society, founded in London in 1660, was a major center for the performance and reporting of experimental work in the mechanics, as well as in the fields of static electricity, optics, magnetism, physiology,

and chemistry. As these areas became more defined, many advancements were made in each field. Chemical experimenters, for example, focused on the classification and isolation of chemical reactions and substances instead of focusing on Newtonian chemical affiliations.

Astronomy: Halley's Comet

Halley's Comet, also referred to as *Comet Halley* or *IP/Halley*, is the best known of the short-period comets. It is visible from Earth every 75 or 76 years with only the naked eye. Halley is the only naked-eye comet that one might see twice in their lifetime. It last appeared to the inhabitants of Earth in 1986 and will next appear in mid-2061.

The comet's habitual returns to our inner solar system have been seen and recorded by astronomers since at least 240 B.C.E. Instances of the comet's appearance have been recorded by the ancient Babylonians, the Chinese, and medieval Europeans, but at the time, the instances were not connected as sightings of the same comet. Its periodicity was not determined until 1705, when English astronomer Edmond Halley made the discovery.

In 1986, when the comet was last visible from Earth, it also became the first comet to be observed in detail by spacecraft. This allowed it to provide the first observational data on the structure of a comet's nucleus and to support a number of longstanding hypotheses about how comets were constructed. Perhaps most notable was the American astronomer Fred Whipple's *dirty snowball* model, which correctly asserted that Halley was composed of a mixture of volatile ices, such as carbon dioxide, water and ammonia—as well as dust. The mission also evolved and improved these ideas. For example, we now know that only a small portion of Halley's Comet is icy—most of it is *dusty*.

Halley's Comet has likely been in its present orbit between 16,000 and 200,000 years, though it is not feasible to numerically calculate its orbit based on the few recorded observations we have. We do know that when this comet approaches the Sun, it expels gas from its surface, and it is knocked slightly off its path. This causes delays of about four days each time it happens. It is thought that comets of the Halley type were originally long-period comets whose orbits were disturbed by the

gravity of the giant planets—at which point they were sent into the inner Solar System. If Halley was indeed of this type, it is likely to have originated at the Oort Cloud, though others have proposed that it came from the area near Uranus and Pluto.

Halley's Comet was the first to be recognized as periodic. Until the Renaissance, it was accepted that Aristotle and his followers had been correct in asserting that comets were disturbances in Earth's atmosphere. This idea was disproven, however, by the Danish astronomer Tycho Brahe in 1577. He used parallax measurements to prove that comets must also occur beyond the Moon. At the time, most of the world did not believe that comets orbited the Sun—instead they believed that they followed straight paths through the solar system.

This is where Newton's friend Edmond Halley comes in. Halley, who was a publisher and editor, published his *Synopsis of the Astronomy of Comets* in 1705. In this work, he used his friend Newton's laws to calculate the gravitational effects of Saturn and Jupiter on cometary orbits. After making this calculation, Halley was able to determine that the orbital elements of a second comet that had appeared in 1682 was the same comet that had appeared in 1531 (observed by Petrus Apianus) and 1607 (observed by Johannes Kepler). He noticed that the same comet returned every 76 years, which we now know to be every 75–76 years. That year, Halley correctly predicted the comet would make its way back to Earth in 1758.

Johann Geor Palitzsch, a German farmer and amateur astronomer, saw Halley's Comet on December 25, 1758. The comet did not pass through its perihelion until March 13, 1759, because Saturn and Jupiter caused a retardation of 618 days. A team of three French mathematicians calculated this effect before its return (with a 1-month error). These mathematicians were Joseph Lalande, Alexis Clairaut, and Nicole-Reine Lepaute. Halley, unfortunately, died before he could view the comet's return for himself. The comet's return also represented the earliest successful tests of Newtonian physics. French astronomer Nicolas Louis de Lacaille named the comet in Halley's honor in 1759.

It is important to note that though Halley's Comet was named after Edmond Halley, others

may have noticed its appearance long before he did. The idea has been raised that first-century Jewish astronomers knew the comet was periodic, according to a passage in the Talmud.

Benjamin Franklin and the Lightning Rod

Benjamin Franklin (1706–1790) is known as one of the founders of the United States and as the inventor of a number of devices that are still in use today. Benjamin Franklin also invented the pointed lightning rod conductor, which was also called a *Franklin rod* or *lightning attractor*. This invention occurred in 1749 and was part of Franklin's pathbreaking explorations of electricity. Although not the first to write about the correlation between lightning and electricity, Franklin was the first to propose a workable system for testing his hypothesis. It was several more years before Franklin performed his reported kite experiment, which, through legend, took place because he was tired of waiting for Christ Church in Philadelphia to finish being built so he could put a rod on top of its spire. (It is important to note, however, that the actual occurrence of this event has been heavily debated).

Later, in the 19th century, the lightning rod was used as a decorative motif. They were embellished with ornamental glass balls and are now a popular collector's item. The balls have been used as weather vanes, but their main purpose is to provide evidence of a lightning strike by falling off or shattering. This helps building owners know if they should check their buildings and ground wires for damage after a storm. The marine lightning rod was also developed soon after Franklin's initial work.

Joseph Priestley

The Englishman Joseph Priestley (1733–1804) was an 18th-century dissenting clergyman, theologian, chemist, natural philosopher, Liberal political theorist, and educator who published over 150 works. Priestley is typically credited with the discovery of oxygen, as he isolated it in its gaseous state. However, Antoine Lavoisier and Carl Wilhelm Scheele also have claims to the discovery.

Throughout his life, Priestley's considerable scientific reputation was contingent on his invention of soda water, his discovery of several *airs* (gases), and his writings on electricity. He named oxygen *dephlogisticated air* at the time. He was determined to defend phlogiston theory and reject what would become the chemical revolution, but this eventually left him isolated within his own scientific community.

Priestley also saw a strong connection between science and his brand of theology. He made repeated attempts to connect Christian theism and Enlightenment rationalism. He attempted to combine determinism, theism, and materialism in his metaphysical texts. He thought that a good understanding of the natural world would promote human progress and bring about a Christian Millennium.

Priestley strongly believed in an open exchange of ideas, and he advocated toleration and equal rights for religious Dissenters. This also led to his cofounding of the Unitarian Church in England. His controversial publications and outspoken support of the French Revolution aroused suspicion from the government and the public. In 1791, he was forced to flee from Birmingham with his family. First the Priestleys went to London in 1791, then fled to the United States, following a mob's burning down his church and home. In the last 10 years of his life, he dwelled in Northumberland County, Pennsylvania.

In addition to his contributions to science, Priestley contributed to pedagogy, publishing works on English grammar, early and influential timelines, and books on history. In fact, his educational works were some of Priestley's most popular. However, his metaphysical works did outpace them. Leading philosophers such as Herbert Spencer, John Stuart Mill, and Jeremy Bentham later credited them as some of the primary sources for utilitarianism.

Charles Augustin de Coulomb

Coulomb's law, also called Coulomb's inverse-square law, describes the electrostatic interaction between electrically charged particles. First published in 1785 by the French physicist Charles-Augustin de Coulomb, the law was essential to the development of the theory of electromagnetism. It is also analogous to Newton's inverse-square law

of universal gravitation. The heavily tested law can be used to derive Gauss's law and vice versa.

The phenomenon of static electricity had been observed and investigated long before Coulomb, however. Ancient Mediterranean cultures knew that certain objects could be rubbed with an animal's fur until they attracted lighter objects. Around 600 B.C.E., Thales of Miletus made observations on static electricity which led him to believe that friction rendered amber magnetic, while minerals such as magnetite needed no rubbing. Unfortunately, Thales was incorrect in attributing the attraction to magnetic effect, but science did later prove a link between electricity and magnetism.

Until 1600, electricity would remain little more than an intellectual curiosity, at which time William Gilbert studied magnetism and electricity and distinguished static electricity (which was produced by rubbing amber) from the lodestone effect. From this, he coined the New Latin word *electricus* (like amber or of amber, from the Greek word *elektron*, which also meant amber). Today, we have the English words *electric* and *electricity*, both of which were printed in Thomas Browne's *Pseudodoxia Epidemica* of 1646.

Several scientists in the early 18th century, including Alessandro Volta and Daniel Bernoulli, suspected that electrical force diminished with distance in the same way that the force of gravity did. These two men measured the force between the plates of a capacitor.

In 1758, Franz Aepinus proposed the *inverse-square law*. Based on this law and experiments with electrically charged spheres, Englishman Joseph Priestley was among the first to propose that electrical force followed this law—similar to Newton's law of universal gravitation, though he did not elaborate on this theory. In 1767, he argued that the force between charges varied as the inverse square of the distance.

Coulomb's Torsion Balance

Continuing with Coulomb's original work, Scottish physicist John Robinson announced that the force of repulsion of two positive or two negative circles varied as $x - 2.06$, thereby solving an age-old question. By the early 1770s,

dependence on the force between charged bodies upon charge and distance had been discovered (yet not published) by the Englishman Henry Cavendish.

In 1785, Coulomb published his first three reports on magnetism and electricity and stated his law. This led to the development of the field of magnetism. Coulomb utilized a torsion balance to study the attraction forces and repulsion of charged particles. He determined that the magnitude of the electric force between two point charges is proportional to the square of the distance between them.

This torsion balance is composed of a bar suspended from its center by a thin fiber, which acts as a very weak torsion spring. When Coulomb performed his famous experiment, he used an insulating rod as the torsion balance, along with a metal-coated ball attached to one end that was suspended by a silk thread. This ball was charged with static electricity, while a second ball with the same charged polarity was brought close to it. The two balls repelled one another, and the fiber was twisted through a certain angle, which could be read on the instrument's scale. Coulomb was then able to calculate the force between the balls and determine his inverse-square proportionality law by knowing how much force it took to twist the fiber through a given angle.

Coulomb's Law

According to Coulomb's law, the magnitude of the electrostatic force of interaction between two point charges is exactly proportionate to the scalar multiplication of the magnitudes of charges. He also asserts that is also inversely proportional to the square of the distance between these two points. The force along the straight line joins the points, and if their two charges have the same sign, the electrostatic force between them will be repulsive, whereas if they have different signs, the force between them is attractive.

Coulomb's law can be stated as a mathematical expression as follows:

$$F_1 = k_e \frac{q_1 q_2}{|r_{21}|^2} \hat{r}_{21} \text{ and } |F_1| = k_e \frac{|q_1 q_2|}{r^2},$$

respectively, where k_e is Coulomb's constant,

$$(k_e = 8.9875517873681764 \times 10^9 \text{ N} \cdot \text{m}^2 \cdot \text{C}^{-2})$$

q_1 and q_2 are the signed magnitudes of the charges, the scalar r is the distance between the charges, the vector $\mathbf{r}_{21} = \mathbf{r}_1 - \mathbf{r}_2$ is the vectorial distance between the charges, and $\hat{\mathbf{r}}_{21} = \mathbf{r}_{21}/|\mathbf{r}_{21}|$ (a unit vector pointing from q_2 to q_1). The vector form of the equation calculates the force $\mathbf{F}_1$ applied on q_1 by q_2 . If $\mathbf{r}_{12}$ is used instead, then the effect on q_2 can be found. This can also be determined by employing Newton's third law: $\mathbf{F}_2 = -\mathbf{F}_1$.

Units

Electromagnetic theory is typically expressed using the standard International System of Units (SI units). Charge is then measured in coulombs, force in newtons, and distance in meters. Coulomb's constant is represented as $k_e = 1/(4\pi\epsilon_0\epsilon)$. The constant ϵ_0 is the permittivity of free space in $\text{C}^2 \text{m}^{-2} \text{N}^{-1}$. And ϵ is the relative permittivity of the material in which the charges are immersed. It is also dimensionless.

Coulomb's law and Coulomb's constant can be interpreted in various terms: One of these is electronic units, also known as *Gaussian units*. In both sets of units, the unit charge (statcoulomb or esu) is defined in a way that leaves the Coulomb constant k to disappear, owing to the fact that it has a value of one and becomes dimensionless.

The other unit is atomic units. In these units, force is expressed in hartrees per Bohr radius, the distances in terms of the Bohr radius and the charge in terms of elementary charge.

There is much more to say about Coulomb's law in terms of its theory and practical applications that space limitations will not enable us to discuss here, including the areas of continuous charge distribution, the system of discrete charges, vector form, scalar form, the electric field, Coulomb's relationship to atoms, and Coulomb's constant. It is most important, however, to note that there are *two conditions for the validity* of Coulomb's law: The charges considered must be point charges, and they should be stationary with respect to one another.

The Enlightenment, Science, and Religion

Physics, referred to early on simply as *science* in many cases, had a large impact on religious views

during the Enlightenment. We have already discussed Priestley's religious views and how they coincided with the Age of Enlightenment, but now let us look at how they played out in society in general.

Much in the religious change of thought revolved around the thoughts of thinkers and theorists such as Newton and John Locke. Their ideas highlighted the transformation of society and of describing knowledge in terms of human experience instead of from a Biblical perspective.

John Locke

Western Europe was rapidly turning to urbanization, due to the wealth coming in from colonialism. Many people left the farms for the cities, and the close proximity of populations allowed thinkers and scholars to meet and share ideas. Large, prominent cities such as Edinburgh, Paris, and London became known as strongholds of Enlightenment thought. Following the decline of Catholicism, English culture flourished and began to produce some prominent engineers, philosophers, and scientists as wealth flowed in from mercantile and colonial ventures in Asia and the New World.

Scholars adopted empiricism during this Age of Reason, and they believed that all theories should be based upon human experience and personal observations. The hand of God was no longer seen behind every phenomenon, and science began to take precedence. Some scholars, like Newton, did feel that there was room for a divine creator, the Uncaused Cause of Aristotle. The world's new definition of knowledge was embedded in every aspect of society, and the rapid accumulation of knowledge led to science being divided into separate disciplines.

Philosophers and scholars rebelled against the restrictions of Christianity and instead used metaphysics and science to question the universe. Europe was becoming secular, and the field of science itself moved away from Biblical absolutism and realism. Philosophers such as Descartes had previously questioned the nature of the soul in the 1600s and had envisioned a universe that was purely mechanical and physical in nature. Descartes believed that the human body and animals were automatons, with the soul alone elevating humanity.

Financial support was found for new research on these topics, and new inventions such as the barometer, telescope, and microscope allowed scholars to make more accurate observations than ever before, while also conducting better experiments as the scientific method was refined. The printing press had made books much cheaper, and roads and improved transportation allowed for the flow of traffic, as well as ideas. Intellectuals such as Leibniz and Newton conducted fierce debates by letter. Scientific societies also provided a place to share and refine ideas, as well as receive constructive criticism.

Conclusion: The Enlightenment and Social Reform

Alongside amazing scientific discoveries, much progress was made in social reform, owing to the work of Enlightenment thinkers. They provided challenges to theocracy and autocracy, which had been fundamental elements of society for many centuries. Commerce and trade vied with agriculture for importance, and Europe became transformed into a host of societies that increasingly pursued the pleasures of life.

The growth of capital also allowed scholars the resources they needed and led to a sense of optimism—particularly, a feeling that humanity could change the world for the better. Philosophers began to try to understand the nature of knowledge itself instead of focusing on abstract musings about the universe and Aristotelian metaphysics. They began to realize that humankind had the capacity to influence nature, and not everything was necessarily foreordained by divine beings and supernatural forces. More and more, humanity was considered to be governed by natural law. Gradually, the natural sciences—chemistry, astronomy, and physics—gave rise to the political and social sciences, as scholars came to believe that the world, including human society, could be understood through methodical observation and study.

PHYSICS, GRAVITATIONAL THEORY

A gravitational theory explains, first of all, why heavy objects fall to the ground; Isaac Newton's (1643–1727) epochal formulation of gravitational theory in the 1680s extended gravity universally on Earth and into the heavens, the realm of astronomy; his laws of motion and his theories in other areas of physics would hold sway for more than two centuries. Subsequently, the move from Newton's *action at a distance* celestial mechanics to local field theories made it appropriate, especially once Albert Einstein's special theory of relativity had emerged in 1905, to seek a relativistic field theory of gravity. A physical field associates a number (or more) to each point in space at a time; hydrodynamics is a familiar example, but most fields are less tangible.

Whereas the first satisfactory theory of gravity of this type was Gunnar Nordström's, in the same years (early 1910s) Albert Einstein (1879–1955) was seeking a generalized theory of relativity to include gravitation. Einstein's 1915–1916 theory, which has come to be called *general relativity*, was revolutionary not only in dethroning the long-reigning Newtonian physics but also in advancing the idea that space-time is curved, indeed variably curved, a claim that only made sense given recent mathematical advances unknown to most

physicists at the time and bewildering to the Euclidean geometry-trained common person. With the bending of starlight by a strong gravitational field, observed by astronomer Arthur S. Eddington in 1919, the seemingly incomprehensible was empirically verified and Einstein took on a prophetic stature in the public imagination. This entry discusses the language and content of Einstein's theory, its relation to experiments, its relation to cosmology, conceptual issues involving the century-long controversy about gravitational energy and conservation laws and a recurring debate about determinism, the question of gravitational exceptionalism versus egalitarianism vis-à-vis other physical fields, and how gravitational theory might be merged with quantum mechanics into quantum gravity.

Language and Content of Einstein's Theory

Einstein's field equations are 10 coupled nonlinear partial differential equations for the space-time metric tensor, which relates small space-time coordinate differences to physical distances and times. (In geography, relating longitude to distance requires the metric tensor.) These partial differential equations relate the metric and its first and second partial derivatives (rates of change with respect to coordinates) to nongravitational energy, momentum densities, and stress or pressure. The equations display some structural similarity to James Clerk Maxwell's (1831–1879) field equations for electromagnetism, but Einstein's equations are nonlinear: The sum of two solutions is not a solution. Both theories admit waves propagating at the speed of light. A novel feature of general relativity is the infinitely greater variety of equally appropriate ways to give numerical labels (coordinates) to times and places. This *general covariance*, the preservation of the form of the laws under basically arbitrary coordinate transformations, requires tensor calculus. Traditional tensor calculus involves a taxonomy of the various ways that physical quantities can transform under change of a coordinate system. A tensor of a certain sort has values relative to a coordinate system, related to values in any other coordinate system by a transformation rule involving partial derivatives. Especially among mathematicians there has been an effort to reformulate tensor

calculus and differential geometry (the calculus-based geometry of curved spaces) using coordinates, but rarely. In key instances, different sets of components of a tensor appear as facets of an invariant abstract entity. This entity is analogous to a Platonic proposition expressed by sentences such as “Snow is white” and (in German) “Schnee ist weiss.” To what degree this *coordinate-free* approach retains classical expressive power seems unclear presently, but the approach is advantageous for global problems.

Already in Newtonian physics, gravity is universal: A point-sized bit of matter experiences (and causes) a gravitational force proportional to its mass—the same mass that appears in Newton's second law determining acceleration. Equality of active and passive gravitational mass with inertial mass suggests a tight connection with space and time. Experimentally, this result could be approximate. Einstein took it as exact in his theory of general relativity, merging gravity into space-time geometry. Hence, one cannot speak objectively of the gravitational force on an object. Particles can be viewed as moving on straight lines (*geodesics*) in a curved space-time.

Einstein took a key feature of his theory to be the lack of preferred inertial coordinate systems, a feature he called *general covariance*. Among physicists this claim has been accepted as basically right, but it has resisted clarification despite decades of effort; the newer term *background independence* covers similar ground. General relativistic space-time geometry generally lacks symmetries—a claim not to be confused with the question of the symmetry of laws, which general relativity has in novel abundance. For earlier theories, the two questions hardly need distinguishing, but for general relativity, conflation has serious consequences for conservation laws.

Gravitational Theory and Experiment

Early observations favoring Einstein's theory over rival theories in the 1910s included its better treatment of the perihelion precession of Mercury (an issue complicated by uncertainties about the matter content of the solar system) and, strikingly, the bending of light in 1919—a phenomenon not readily accommodated by Newton's theory and clearly not predicted by Nordström's theory. The

1950s experiment by Robert V. Pound and Glen A. Rebka, Jr. observed the gravitational red/blueshifting of light. In 1981 Russell A. Hulse and Joseph H. Taylor, Jr. found that a binary pulsar orbit was decaying according to the gravitational radiation predicted by Einstein's equations, in contrast to most other theories of gravity. Gravitational time dilation is crucially used in global positioning systems.

In local field theories with laws having at least the symmetries characteristic of special relativity (including general relativity), waves travel at light speed. Thus it would take a billion years to see or feel (gravitationally) an event a billion light years away. Cosmic expansion, according to Big Bang cosmology, complicates that result slightly. A conceptual wrinkle arises, owing to general relativity's radical relativity of simultaneity: One could, for example, define simultaneity using a past-facing hyperboloid instead of a roughly flat hypersurface, and so regard events 10 billion light years away and 10 billion years earlier (by naïve definitions) as not very far in the past, if one wishes. Hyperboloidal time coordinates are useful for finding approximate solutions of Einstein's equations using computers. In the 2015–2016, after decades of effort in the laser interferometer gravitational-wave observatory (LIGO) program (among others), gravitational radiation was detected. Only large, fast-moving masses produce appreciable radiation, such as binary systems involving neutron stars or black holes.

Gravitational attraction so strong that even light cannot escape is predicted by the theory of general relativity in some contexts. In the 1960s, the tendency of a sufficient quantity of localized matter to collapse toward a singular point because of gravity was found to be generic, using new global techniques employed by Roger Penrose and Stephen Hawking. Gravitational collapse tends to hide itself behind a horizon, an outermost surface on which *outbound* light remains at fixed radial distance. It is therefore difficult to know much about matter collapsed into a black hole. Whereas experimental particle physics can largely ignore gravity, efforts beginning in the 1970s to embed particle physicists' quantum field theory in a gravitational environment has encouraged an analogy (or more) between black holes and thermal physics.

Cosmology

The typical cosmological model describes space as homogeneous and isotropic (the same in all places and directions), an assumption motivated by pragmatism (tractable mathematics), empiricism (astronomical data fit tolerably well), and naturalistic philosophy (denying a *special* world). Attempting to express tensor calculus verbally, one can say that the universe is expanding, or that everything is receding from everything else. This expansion redshifts light, including the cosmic microwave background and light from stars, increasingly with distance. Extrapolating backwards and trusting Einstein's equations beyond their expected realm of validity (for one would expect quantum gravity effects to make an important difference) implies moments of arbitrarily great density and temperature. The Big Bang singularity “at” $t = 0$, however, is not a consensus scientific explanation of the origin of the universe; experts typically expect quantum gravity to smooth out such a backward extrapolation. This debate has little theological relevance: While the Big Bang does not support a creation event, quantum gravity's removing the singular Bang from the model wouldn't exclude creation from reality either. Claims of cosmic fine tuning for life continue to develop and be refined; some might be alternatively explained by way of a multiverse.

Big Bang nucleosynthesis uses nuclear physics, with the universe assumed near equilibrium in a hot expanding phase, to predict the proportions of light element isotopes (hydrogen, helium, lithium, etc.). Leaving heavier elements to be predicted by nuclear astrophysics including supernovae, Big Bang nucleosynthesis predicts light element abundances rather well at the time of writing.

Although an expanding universe would be expected to decelerate because of gravitational attraction, several puzzles, including how flat space is, could be resolved by positing vastly more rapid expansion early on. This *inflation* admits various moderately plausible theoretical explanations in terms of one or more fields, dubbed the *inflaton*, which, however, typically lack independent support. Inflaton behavior constitutes an effective positive *cosmological constant* Λ (capital Greek letter lambda), a modification to his field equations that Einstein suggested in 1917.

Since the late 1990s, a combination of two large-distance empirical puzzles for general relativity has opened the field theoretically to explore other theories. Since the mid-20th century, an awkward find for general relativity at large distances has been *dark matter*, the inferred cause of the observed failure of galaxies to disintegrate, despite the insufficiency of visible matter to bind them. The name *dark matter* implies that the gravitational laws typically were not blamed. Remarkably, in 1998, observations of supernovas indicated that the universe is currently in a state of accelerating expansion ($\Lambda > 0$). (The alternative proposal of inhomogeneity has not fared well.) This phenomenon (or its explanation) is *dark energy*. Whether dark energy is gravitational or material is unclear. The combination of dark matter and dark energy, both arguably flawed predictions on large distances, broke the nearly universal consensus on general relativity. Though Einstein's theory remains favored, there is increased work on alternative theories.

Interpretive Questions

In post-1910s physics, the conservation of energy and momentum are derived from the uniformity of natural laws over time (energy) and place (momentum). Formally, the same treatment works for general relativity, but the result is a *pseudotensor*: The descriptions of energy and momentum in different coordinate systems appear inequivalent. Even the absence or presence of gravitational energy at a point is not invariant. One appears to have a choice of saying that gravitational energy exists but is not objectively at specific space-time points (*nonlocalizability*, the mainstream view), or does not exist despite the formal conservation of material energy + gravitational pseudo-energy in any coordinate system, or is infinitely multiple (a 2000s idea). The popular *quasi-local* program aims to localize energy to finite regions.

Einstein's process of discovery included the *hole argument*, by which he temporarily convinced himself that generally covariant theories were indeterministic: One past has multiple possible futures. This concern was resolved by way of the *point-coincidence argument*, which individuates space-time points by their material contents (somewhat as in Gottfried Wilhelm Leibniz's

thought from the 1710s), not primitively as the hole argument assumed (akin to Newton's ideas at times). For reasons likely involving coordinate-free differential geometry as well as general relativity's historiography, a revived hole argument appeared in philosophy in the 1980s and remains widely discussed. While no one denies determinism (locally) in Einstein's theory, ways to make space-time points' identities depend on physical properties vary.

A longstanding divide concerning gravitation is whether gravity is exceptional or is basically like the other fundamental interactions (electromagnetism and the weak and strong nuclear forces). The former view is usual among specialists in general relativity; the latter egalitarian view is usual among particle physicists, including luminaries such as Richard Feynman and Steven Weinberg. One's view on this issue affects many other questions. First, does one expect dramatic global consequences and hence need global techniques including coordinate-free geometry? Second, what modifications or alternative theories are plausible—theories generalizing metric geometry or generalizing a theory of a field/particle that exactly fits a particular slot in particle physicists' taxonomy? Third, how should one merge gravity with quantum mechanics into quantum gravity? General relativists have preferred quantization techniques admitting dramatic or global novelty, whereas particle physicists have tended to assume small perturbations. Fourth, how does one approach conceptual puzzles about general relativity—for example, about energy (non)conservation, or the apparent absence of change in some quantum gravity programs—are they insights or, at best, options? Fifth, what does one consider relevant, insightful, accidental, important, or mistaken in the history of general relativity? In physics this divide started weakening in the 1970s with the advent of supergravity and later (super)string theory. Supergravity ascribes to gravity a *gravitino* partner that is fermionic, satisfying the Pauli exclusion principle.

Since the 1990s, historians of physics have made an exhaustive study of Einstein's process of discovery, including unpublished notebooks. A key result is the importance of a second line of thought in Einstein's work, which he retrospectively suppressed: Besides his mathematical

strategy of principles such as general covariance, generalized relativity of motion, and the equivalence of gravity and acceleration, Einstein employed a physical strategy including conservation laws and analogies to Newtonian gravity and to electromagnetism. Einstein retrospectively credited the mathematical strategy with success and further pursued into theories aiming to unify electromagnetism into the same framework, but this work is generally considered unsuccessful. It turns out that particle physicists' rigorous rederivation of Einstein's equations (c. 1938–c. 1972) uses the same kinds of ideas as Einstein's physical strategy. Hence, whether or not Einstein's physical strategy succeeded in his hands, it does work.

Quantum Gravity

All the other fundamental interactions are described by quantum field theories. Presumably gravity also must be *quantized*, perhaps on pain of contradiction. While guidance from experiment would be ideal, that prospect seems remote at the time of writing. Whether gravity is exceptional or just another force strongly influences one's views about quantization.

Gravity as the great exception is likely to yield dramatic, novel, fundamentally nonlinear phenomena requiring Hamiltonian (*canonical*) quantization or path integration. Loop quantum gravity continues this tradition effectively. A puzzle of apparently losing time and change has accompanied canonical quantum gravity since the 1950s: It has been difficult to identify the physically real content, which tends to get submerged in the conventional. A reforming viewpoint since the 1980s suggests recovering early 1950s mathematically rigorous equivalence to the four-dimensional symmetry of Einstein's equations.

Gravity as just another fundamental force is likely yield modest perturbative effects. This project saw considerable effort from particle physics in the 1960s and 1970s but produced incurable infinities (*nonrenormalizability*). This problem might be resolved if there is a special fermionic partner(s), called a *gravitino*, of the gravitational particle (graviton) that introduces minus signs so as to cancel bad terms from gravity, as in 1970s+ supergravity. The project further developed into

(super)string theory. Any such *supersymmetric* particles remain elusive empirically, however. A 1990s+ shift to *effective* field theories indicates that the old infinities are not fatal if new physics might become relevant at sufficiently high energies. On that view, we can know enough about gravity without knowing everything.

PHYSICS, MIDDLE AGES

The Middle Ages, also referred to as the *medieval period*, took place from approximately the 5th to the 15th century C.E. It began with the gradual collapse of the Western Roman Empire and was followed by what is now known as the *Renaissance and the Age of Discovery*. It is the second of

three major stages of Western history: antiquity, the medieval period, and the modern period. The medieval period itself is divided by historians into the Early, High, and Late Middle Ages. This entry describes the origins of medieval physical theories and practices in the work of earlier scholars and the efforts made during the Middle Ages to preserve and build upon ancient knowledge. Prominent thinkers of the period in Europe and in the Middle East and their notable achievements are discussed. A section on the growth of trade throughout and beyond Europe and the founding of centers of learning is followed by an exploration of the scientific and mathematical culture of the High and Late Middle Ages, including a description of the work of scholars at Merton College, Oxford, in helping to establish the foundations of the scientific method.

Philosophers/Physicists Influential on Thought in the Middle Ages

The Middle Ages inherited a large amount of knowledge from the age of antiquity, including the philosophies of Aristotle and other Greek thinkers, and work in ancient astronomy, owing to the efforts of the polymathic scholar Ptolemy, who lived in the 2nd century C.E. Aristotle, like philosophers before him, stated that terrestrial and celestial realms were separated by the orbit of the Moon and only differentiated themselves by their unique physical behaviors. Aristotle's terrestrial physics ideas were founded on the existence of four elements (fire, water, air, and earth) and the assertion that every motion requires a specification of cause for its motion.

Aristotle believed that there were two main types of motion: violent motion (when an object is removed forcibly from its natural place) and natural motion (the motion arising from the nature of an object). This model dictated that the natural place of the element earth was at the center of the cosmos and that Earth, the human domain, was the center of the heavens.

Although the terrestrial realm featured constant change, the heavenly bodies moved in their circular, uniform orbits and were unchanging. Ptolemy, drawing on a massive amount of astronomical data, modeled the orbit of each heavenly body with a system of circular motions. He was

often forced by new data to make additions to his model, such as his *eccentric* model and his *equant* model.

Although this work was enormously valuable, it was lost to the West over the course of the decline and dissolution of the Roman Empire. A number of Islamic scholars, however, were interested in it and translated it into Arabic, where they studied it extensively, eventually making their own major innovations in matter theory, optics, astronomy, and mathematics (including what we still refer to as *Arabic numerals*).

Around the 8th century, the Syrian astronomer al-Battani improved upon Ptolemy's orbits of the Moon and Sun, created a revised catalogue of stars, and constructed astronomical instruments. Avempace (an Arab Andalusian also known as *Ibn Badja*) developed a philosophy first outlined by Neoplatonist philosopher John Philoponus in the 6th century C.E. This argument claimed that the amount of time it took for an object to fall was proportional to its weight. After the Muslim conquest of Hispania during the 8th century, ancient knowledge came to the Latin west once again. Arab scholars such as Averroes (also known as *Ibn Rushd*) became interpreters of Aristotle—providing translations that were much closer to the original texts than they previously had been.

Early Medieval Society: The Dark Ages

The early medieval period lasted from about 500 to 1000 C.E. and is commonly regarded as the *Dark Ages* because of the barbarism and ignorance that had become prevalent across Europe. Yet even this era saw advances in science and technology; unfortunately, most of this information was lost due to constant warfare on the European continent.

It was monastic study that kept literacy and learning alive. Although most monasteries centered their pursuits on the Bible and early Christian theologians, the monks also studied astronomy, geometry, medicine, and mathematics. In the secular realm, tradesmen also made advances in the fields of science and mechanics. It is true, however, that little progress was made in terms of the scientific method. In Europe, classical thought and philosophy were mostly forgotten—though they were preserved in Islam and Byzantium.

Medieval Thoughts on Space

Following in the path of Aristotle, medieval scholars believed that the celestial realm was one of unchanging perfection and that the Moon, the planets, the Sun, and the sphere of the fixed stars rotated around the Earth in their own celestial spheres. Ptolemy added epicycles in addition to Aristotle's concentric spheres, which led to medieval astronomers calling heavenly bodies either *total orbs* or *partial orbs*.

These orbs, it was believed, could communicate rotational movement to one another with no resistive force and were composed of quintessence or ether, which was conceived as a transparent, ageless substance. This is where the Christian God came into play. Taking the place of Aristotle's *Unmoved Mover*, he was believed to be beyond the outermost sphere of the fixed stars and to have the ability to impress an impetus on each orb at the moment of creation. Because there had been no resistance put upon them since that time, they were still rotating. Nicole Oresme and Jean Buridan, two 14th-century French scholars, considered the possibility of using a rotating Earth to explain the diurnal motion of the fixed stars, but their arguments did not go very far, as they themselves remained unconvinced.

The Middle East

After the Roman Empire was divided into Eastern and Western halves by the emperor Constantine in the 4th century C.E., the Western Roman Empire lost much of its history. In the Middle East, Greek philosophy was taken up by some scholars in the newly created Arab Empire. A period of Muslim scholarship arose with the spread of the Islamic religion in the 7th and 8th centuries, and this Islamic Golden Age lasted until the 13th century. The scholarship was furthered by the use of a single language, Arabic, as well as access to Greek texts from the Byzantine Empire and Indian sources of scholarship.

The Eastern, or Byzantine, Empire housed centers of learning such as Constantinople, while Western Europe's knowledge was preserved and cultivated in Christian monasteries until medieval universities were developed in the 12th and 13th centuries. Monastic schools taught ancient texts

and new works on practical subjects such as time-keeping and medicine.

Muslim scientists placed emphasis on experimentation, leading to an early scientific method being developed in the Muslim world and a considerable progress being made in methodology. Al-Haytham (Alhazen) began experiments in optics in ca. 1000 in his *Book of Optics*. He is known as the founder of optics because of his empirical proof of the intromission theory of light. He has even been called the *first scientist* for his work in developing what we now call the scientific method.

The most important use of this scientific method by Muslim scientists was to host experiments to distinguish between competing scientific theories comprised within a generally empirical orientation. In the field of mathematics, Persian mathematician Muhammad ibn Musa al-Khwarizmi created the concept of the algorithm (and donated his name to the field), while the term *algebra* comes from *al-jabr*, the leading title of one of his publications. What we commonly refer to as Arabic numerals originated from India, but Muslim mathematicians gradually refined the number system by introducing such edits as decimal point notation.

Persian scholar Al-Razi contributed to medicine and chemistry, and Sabian mathematician Al-Battani made excellent contributions to the fields of mathematics and astronomy. Al-Battani improved the measurements of Hipparchus, as they were kept safe in the translation of Ptolemy's *Hè Megalè Syntaxis* (The Great Treatise), translated as *Almagest*. He also made improvements to the measurement of the precession of the Earth's axis. The corrections made to the geocentric model by al-Battani, Ibn al-Haytham, Averroes, and the Maragha astronomers such as Nasir al-Din al-Tusi, Ibn al-Shatir, and Mo'ayyeduddin Urdu are similar to the heliocentric model later introduced by Nicolaus Copernicus in 1543. Heliocentric theories may have also been discussed by several other Muslim astronomers such as Ja'far ibn Muhammad, Abu Ma'shar al-Balkhi, Najm al-Din al-Qazwini al-Katibi, Abu-Rayhan Biruni, Quth al-Din al-Shirazi, and Abu Said al-Sijzi.

In the field of chemistry, Muslim chemists and alchemists play an important role, and scholar Jābir ibn Hayyān is considered by many to be the father of chemistry. His works later influenced

Roger Bacon, who introduced the empirical method to Europe.

There were many other famous Islamic scientists from this period, all of which will not be named, though we will mention Ibn Sina (Avicenna), who is thought to be the region's most influential philosopher, as he pioneered the science of experimental medicine and became the first physician to conduct clinical trials.

Islamic science began to decline by the 12th and 13th centuries, due to the Mongol conquests, which destroyed many universities, libraries, and hospitals. The end of the Islamic Golden Age is marked by the destruction of the intellectual center of Baghdad, the capital of the Abbasid caliphate in 1258.

The Expansion of European Exploration and Thought

During the 9th century, Western Europeans came to recognize that systemized education was the key to prosperity and unity. In his period, known as the Carolingian Renaissance, the Frankish king Charlemagne (Charles the Great, crowned as Emperor of the Romans in 800 C.E. by Pope Leo III) sought to establish knowledge as an integral part of medieval society. He may have been brutal in war, but he was a great believer in education, art, and culture, and he used the Catholic Church to transmit this information to the public. Although he was himself illiterate, he ordered the translation of many Latin texts and promoted the study of astronomy.

In England, a monk called Alcuin of York (ca. 724–804) established a system of education in theology, art, geometry, arithmetic and astronomy. He also promoted the establishment of schools. However, his and Charlemagne's goals would be ended by Charlemagne's death and the end of the Frankish Empire (and the beginning of barbarian incursions). However, some centers of learning clung tightly to the pursuit of scholarship, giving rise to a number of extraordinary thinkers in the years that followed.

The High Middle Ages

The period from 1000 to 1300 is referred to by historians as the High Middle Ages, when the long cycle of wars in much of Western Europe began to

diminish. Populations grew, and Christianity provided a unifying force and a sense of shared identity across the continent.

Sharing of ideas (promoted through trade) was common, and ideas were brought to Western Europe from the Arabic empires. Because the Muslims had translated many ancient Greek texts into Arabic, scholars from around Europe were able to translate them back from Arabic into Latin. This way, Greco-Roman knowledge passed through Europe, where places of academic study (*studium generale*) were becoming universities. Many scholars, such as Gerard of Cremona (c. 1114–1187) learned Arabic so they could complete these translations.

In the 12th century, *studium generale* were emerging across Western Europe, combining the knowledge of the ancient Greeks with new discoveries by Muslim scientists and philosophers. They drew scholars from near and far, and their unique curriculum inspired the basis of Christian scholasticism. Although most of the study turned toward theology, the schools also began to integrate scientific empiricism.

Great thinkers of this period included such men as Robert Grosseteste, Thomas Aquinas, Roger Bacon, and William of Ockham—who all worked diligently to perfect and refine what we know today as the scientific method.

Thomas Aquinas was extremely interested in using philosophy to prove the existence of God; he also oversaw a change from Platonic reasoning toward Aristotelian empiricism.

Oxford's Francis School was founded by Robert Grosseteste, who was one of the major contributors to the scientific method. He began to promote the dualistic scientific method as proposed by Aristotle. Grosseteste had an idea that composition and resolution involved prediction and experimentation. He believed that observations could be utilized to proposed universal laws and predict outcomes. Grosseteste was one of the first scientists to use this method as an empirical process, and his ideas influenced Galileo and filtered into the 17th-century Age of Enlightenment. However, the greatest impact on the scientific method was made by Grosseteste's pupil, Roger Bacon.

Roger Bacon was one of the greatest minds of the medieval period and a refiner of the scientific method. He took the works of Aristotle, the Islamic

alchemists, and Grosseteste and used them to propose the idea of induction as the key element of empiricism. He described the method of observation, the hypothesis, and experimentation, noting that results should always be independently verified. He documented all notes in detail so that his experiments could be repeated. Today, any student who writes an experimental paper must use this method.

The Late Middle Ages

By the time of the late Middle Ages (1300–1500), a revival of science and learning in the West was under way. A 13th-century mathematician by the name of Jordanus de Nemore had pioneered a series of studies revolving around static bodies. Along with study levers, he also analyzed the (lower) apparent weight of a mass that was static on an inclined plane.

William of Ockham, in the 14th century, proposed his idea of parsimony and the famous principle of *Occam's razor*, which is still used by scientists today to determine answers between conflicting explanations. Around the same time, Jean Buridan developed the idea of impetus, a concept that predated Newtonian physics and inertia (and challenged Aristotelian physics).

Despite the fact that the church condemned several radical interpretations of Aristotle's work during the late 13th century, there was a flurry of activity around these activities during the next century, particularly revolving around the subject of motion. Merton College at Oxford and the University of Paris became centers of activity for this research. Prominent mathematicians included John Buridan and Nicole Oresme in Paris and Richard Swineshead and Thomas Bradwardine in England.

Merton College

In England, academicians at Merton College, Oxford, presented a distinct separation between *dynamics*, in which the causes of motion are specified, and *kinetics*, in which motion is described. They examined the dynamical problems occurring in the context of Aristotelian physics, such as the problem of projectile motion.

Many other advancements were made in kinematics, which is the release from the search for causation. The Mertonians developed the concept

of velocity in analogy with the idea of the intensity of a quality (such as the greenness of grass). They also made sense of the difference between nonuniform (accelerated) and uniform (constant velocity) motion. The Mertonians also introduced the first instance of the *mean velocity theorem*, which gave the ability to compare uniform motion to constant-acceleration motion.

Mertonians explained their analyses of motion through the use of words, but other scholars used graphical techniques to explain their theories. Perhaps the most impressive presentation of the mean speed theorem was given by Oresme. He recorded the duration of motion along a subject line and showed the intensity of the velocity as a sequence of varying vertical line segments. Although his work was predominantly abstract (rather than based on experimentation), it helped to inspire Galileo's later work in kinematics.

PHYSICS, 19TH CENTURY

The 19th century was an era of rapid growth and transformation in physics, with a quest for the mathematical laws behind observed phenomena and an increased emphasis on quantification. The

establishment of well-funded institutes housing laboratories for conducting physical research both for private concerns and for the state gave rise to sophisticated technologies and the elicitation, study, and measurement of a wide range of phenomena. Foremost, perhaps, among scientists' goals was the creation of a unified physics—the formulation of the fundamental laws that govern all physical phenomena. Physics also catered to the needs and imaginations of different fields—political, military, and commercial—within the expanding and burgeoning industrial nations. During this period, the so-called imponderables (magnetism, electricity, heat, and light) were the main objects of study. As the century advanced, these were treated as having originated from the same fundamental source of energy but with different manifestation. At the same time, the ancient notion of the ether, a substance supposed to pervade all space beyond the sphere of the moon and to transmit light and heat, came into question.

This entry focuses on several areas of advancement in physics during the 19th century, including magnetism and electricity, heat, radiation, thermodynamics, elasticity, dynamics, hydrodynamics, and optics. Other domains of physics in which major developments occurred during this period include crystallography, capillarity, diffusion, viscosity, aeromechanics, acoustics, kinetic theory of gases, velocity of light, photochemistry, fluorescence, and photometry. Owing to space limitations, a detailed account of the latter topics is beyond the scope of this entry. Readers are encouraged to consult the bibliography below for further information.

Key Developments

The study of electric currents received a major boost with the invention of the *Voltaic pile*, the electric battery created by Alessandro Volta in 1800. Shortly thereafter, the wave nature of light was proposed and demonstrated by Thomas Young in 1801, based on which the phenomenon of wave interference was derived. Young was ably and experimentally supported by Augustine-Jean Fresnel, who contributed significantly in establishing the wave theory of light. Peter Ewart, in a paper published in 1813, gave evidence in support of the conservation of energy. Hans Christian Orsted observed in 1820 that a

magnetic force is developed by a conductor carrying an electrical current. At approximately the same time, it was discovered by Andre-Marie Ampère that two electric currents running parallel exert forces between themselves. In 1821, the analysis of the energy of a system expressed in terms of coordinates and momenta was initiated by William Hamilton, and his equations became known as the Hamilton's function. In the same year, an electricity-powered motor was built by Michael Faraday, while in 1826, Georg Ohm stated the law of electrical resistance, which expressed the relationship between current, resistance, and voltage in an electrical circuit. In the subsequent year, Brownian motion, as it came to be called, was discovered by the botanist Robert Brown. He hypothesized that the waterborne pollen grains that he observed under a microscope underwent constant movement due to collisions with the fast-moving molecules or atoms of which the water was composed. In 1831, the process of electromagnetic induction was discovered by Faraday, suggesting that magnetism can give rise to electric current or potential. The independent discoveries of Joseph Henry and Faraday on electromagnetic induction formed the basis for the inventions of the electric generator and the electric motor, respectively. Self-gravitating ellipsoids rotating uniformly were discovered in 1834 by Carl Jacobi. In the same year, John Russell found in Edinburgh's Union Canal a *soliton*, or solitary nondecaying water wave. He then went on to study the dependence of the wave velocities of solitary water waves on water depth and wave amplitude. The canonical equation of motion was proposed in 1835 by William Hamilton. In the same year, the Coriolis effect was deduced by Gaspard Coriolis after careful theoretical examination of the mechanical efficiency of the waterwheel. The effect, put simply, is that a rotating system experiences a force that acts perpendicular to the direction of motion and the axis of rotation. Hence, moving objects tend to be deflected to the right in the northern hemisphere and to the left in the southern hemisphere. A paper on conservation of energy was written in 1841 by Julius Robert but was rejected for publication. A few years later, in 1847, the principle of conservation of energy was independently proposed by Hermann von Helmholtz, who was credited with its formulation. In 1842, the Doppler effect, so called, which concerns the increase or decrease in the

frequency of sound, light, or other waves when source and observer move toward, or away from, each other, was stated by Christian Doppler. In 1851, Léon Foucault's pendulum showed the rotation of earth. The first half of the century saw significant advancements in continuum mechanics (e.g., for fluids), Navier-Stokes equations, and for solids the laws of elasticity. Of the many influences on the development of physics in the 19th century, the following are the most influential.

Heat

The self-taught physicist and instrument designer Guillaume Amontons is credited with the invention (1699) of the earliest air thermometer. Subsequently, with the thorough works of Victor Regnault (1841) and H. G. Magnus (1842) on the thermal compression and expansion of air, studies on thermometry came into prominence. The Carnot function (named for the engineer Nicolas Léonard Sadi Carnot), describing the relation between the amount of heat produced by a source of heat and the work that can be done by it, had been put to use in various ways by stalwarts like James Prescott Joule, Hermann von Helmholtz, and Benoit Paul Émile Clapeyron. The series of works on temperature and its measurements by William Thomson, Lord Kelvin, finally disposed of the subject. On the practical front, thermometry was significantly enriched through the efforts of Pierre-Louis Dulong and Alexis-Thérèse Petit (1818) through their work on the measurement of mercury expansion. This work was suitably supported by Regnault.

The memoir by Fourier of 1822 was responsible for the generation of the theoretical concept of heat conduction, which subsequently went on to illuminate much more of physics. This treatment has been successively dealt with by many of the mainstream thinkers of the time such as Kelvin, Siméon Denis Poisson, and others. It was Kelvin whose efforts resulted in the origin of the concepts of ingenious methods of sinks and sources. Following Fourier, greater attention was paid to earth's heat conduction. On the experimental side, in 1853, Gustav Wiedemann and Rudolph Franz could determine the relative heat conduction for the metals. They were able to show the existence of parallel gradation for the conductivity of electricity and heat. The works of Anders Jonas Angstrom, Franz

Ernst Neumann, and James David Forbes were instrumental in establishing heat conduction measuring absolute methods. Heinrich Friedrich Weber in 1880 devised a lamellar method that can be applied to fluids.

In 1763, the research work of Joseph Black was important in the completion of the work on practical calorimetry. The concepts of chemical, latent, and specific heats were experimentally enriched by the valuable work of Regnault. The approximation of atomic heat constancy for the elements was discovered in 1819 by Dulong and Petit. In 1875, Weber went on to interpret the apparently exceptional cases for boron, carbon, and silicon. This was followed by Regnault in 1840 for sulfur. In 1831, the law was applied to compound bodies by Neumann. Joule in 1844 was able to show that the component specific heats in many cases can be treated additively with the specific heat. Particular mention should be made of Robert Bunsen's ice calorimeter of 1870.

Radiation

With the thermopile reaching the hands of the Italian physicist Macedonio Melloni, the concepts of thermocrosis, diathermacy, and heat radiation gained prominence. The questions on heat and light identity were forever put aside by these researches. In 1878, the invention of Samuel Pierpont Langley's bolometer put the subject to a greater height with regard to precision. The laborious attempts of E. Becquerel and H. Becquerel and John Herschel on the survey of heat spectra ultimately led to the formulation of Langley's charts. The whole subject was perhaps pervaded in 1860 by Gustav Kirchhoff with his Kirchhoff's laws. These laws in their earliest probable forms were anticipated by the Scottish physicist Balfour Stewart as early as in 1857. Josef Stefan in 1879 tentatively formulated black body radiation in relation to temperature. In 1884, Boltzmann went on to further strengthen this. Among other inventions worth mentioning in this regard are Alexander Graham Bell's photophone and William Crooke's radiometer. The radiometer had been put to use by many important figures like Ernest Fox Nicholas and Gordon Ferrie Hull, James Clerk Maxwell, and Pyotr Nilolayevitch Lebedev in his actual measurement of light pressure. In 1838,

Claude Pouillet came up with the first ever estimation of solar radiation constant at earth. Angstrom in 1886 and Langley in 1884 went on to devise other pyrheliometric methods.

Thermodynamics

The vis viva of 1686 constituting the old Leibnizian principle was broadened and fruitfully interpreted through thermodynamics. To begin with, the experiments of Humphrey Davy (1799), Benjamin Thompson, and Count Rumford (1798) set the tone for the domain of thermodynamics. It almost leaped with the computation of mechanical equivalent of heat by Julius Robert von Mayer, and an epoch was marked when Joule came up with the series of judiciously varied and precise measurements of heat (in 1843, 1845). Helmholtz proposed and spread his theory of conservation of energy to encompass the whole of physics following these discoveries. Prior to this, the early part of the century saw Carnot inventing the reversible thermodynamic cycle. The theory of equilibrium for two bodies in mutual action, or the reversible thermodynamic cycle, made huge contributions to modern physics. The efficiency of engines derived from the point of temperature criterion was deduced by Carnot. The geometrical method of representation as proposed by Clapeyron is used today universally. However, Josiah Willard Gibbs with his suggested new coordinates in 1873 allowed it to be used more flexibly. But more work needed to be done in defining the value of transformation so as to bring in harmony between the first law of thermodynamics and the ideas of Carnot. This was just what Rudolf Clausius did in 1850, supported by Kelvin and William J. Macquorn Rankine in the following year. Rankine's broader energetics treatment has been the basis of many subsequent discussions. The investigation on the thermodynamic solution of solids and gases was initiated as early as 1858 by Kirchhoff, who introduced an original method of treatment. Most of the objections to the second law of thermodynamics were dispensed with by Clausius, who was successful in defending even the objections associated with radiation. The law that came nearest in logically justifying the second law of thermodynamics is the elementary statistical mechanics principle of Gibbs, which he proposed in 1902. The first and second laws of

thermodynamics have ubiquitous applications. Some of the interesting instances include the concept and properties of an ideal gas, Kelvin and Joule's experiment to show the physical departure from ideality. The difficulties encountered by Louis Paul Cailletet and Raoul Pictet in liquefying incompressible gases were not faced by James Dewar and Morris William Travers or Karol Olszewski for hydrogen coercions. Further examples include broader treatment of evaporation and fusion, from the calculation of under pressure melting point of ice by James Thomson in 1849, treatment of sublimation by Kirchhoff in 1858, and Kelvin's equation (1883) based vast chapter on thermo-elastics. Besides, there were discoveries of liquid and gaseous state continuity in 1869 by Thomas Andrews; Émile Amagat's experimental prowess in furnishing deeper insights into the laws of physical gases and Johannes Diderik Van der Waals's great work of approximation in 1873 that almost closely predicted the observed facts. The further extension and development of thermodynamics was yet to take place that mainly concerned the chemical systems. Many thinkers at the same time recognized the thermodynamic potential and its analytical power. Some of the important contributions were made by Gibbs, who in 1876 proposed for both adiabatic and isothermal potential, the characteristic functions of Helmholtz in 1882. Gibbs made the most of the new research possibility originating with complete contrast to virtual displacement of *mechanique analytique* and the introduction of the modification of virtual thermodynamics. Without the strong mathematical forces, Jacobus Henricus van 't Hoff came up with his simple and marvelous application of the second law of thermodynamics and propounded a new solution theory based on interpretations of experiments of François-Marie Raoult and Willhelm Pfeffer. This became the basis for experimental investigation of chemical physics. Gibbs's highly generalized chemical statistics brought early success when applied to the phenomenon of dissociation proposed by Henri Sainte-Claire Deville in 1857, and subsequently, it was followed by Gibbs, Pierre Duhem, and Max Planck deducing in succession appropriate equations. The law of mass action (1879), based on research by Cato Guldberg and Peter Waage, received a theoretical basis in case of dilute solutions through the works of Planck.

Elasticity

The theory of elasticity that has made longstanding contributions to physics and has become integral throughout the whole discipline can be traced to a 19th-century creation. In 1807, Thomas Young had recognized shearing force and brought about the useful concept of modulus. Earlier experimental indications had come from Charles-Augustin de Coulomb (1776) in his attempted analysis of torsion and flexure; Leonhard Euler and Jacob Bernoulli's (1742) treatment of vibrating bars, Bernoulli's proposal of the elastic curve along with the works of Edme Mariotte (1680), Robert Hooke (1660) and Galileo Galilei (1638). Claude-Louis Navier's equations of elastic potential energy and elastic displacement enhancing the molecular hypothesis commenced around 1821 that on the broader lines marked the beginning of establishment of the elasticity theory. However, Augustin-Louis Cauchy's (1827) brilliant generalizations soon discredited this startling advancement. Among the valuable contributions he made to the field are strain quadric and stress quadric, six component strains and six component stresses. He also happened to reduce the components to three principal strains and three principal stresses. He explained the ellipsoids and some of the most indispensable concepts of the elastic physics of modern day. Cauchy came to his conclusions and equations aided by molecular hypothesis as well as oblique stress analysis across an interface. These methods gave rise to 15 elasticity constants in the most general case. In the similar time, simultaneous independent contributions came from Poisson (1829) and Clapeyron (1828). In 1837, George Green introduced another fundamental and independent method in elastics. He tried to explain the potential energy of the closed system based on the virtual displacement principle of Joseph-Louis Lagrange. This method was further enhanced through the contributions of Neumann (1885), Kirchhoff (1876), and Kelvin (1856) leading to the formulations for the aeolotropic medium, 21 constants which could be reduced to two for the simplest case. In 1828, Poisson first deduced isotropic medium wave motion. He happened to show the occurrence of different velocity constituted transverse and longitudinal waves. The wave motion problems treated by Green in 1842 for the

aeolotropic media came under significant and strong criticisms from Christoffel in 1877 and Blanchet (1840–1842). The case of radial vibrations for a sphere was treated by Poisson in 1828. Alfred Clebsch in his work of 1862, *Vorlesungen*, generalized in solids, the free vibrations theory. The whole subject was perhaps overhauled with longstanding and continual efforts of de St. Venant (1839–1855), providing the major thrust to elasticity. His works were supported by Clebsch in 1864 and by Navier and François Moigno in 1863. The fundamental significance of shear was adequately asserted by him. In 1855 and 1856, the flexure and torsion of prisms in their complete form was provided through the profound and intricate researches of Adhemar Jean Claude Barré de St. Venant. In either case, the stressed-solids right sections were shown to be curved wherein the curvature could be specified succinctly. The first case superseded the inadequate torsion formula of Coulomb, and the latter case reduced flexural stress to a coupled and transverse force. Among the other notable contributions to the field of elasticity made in the 19th century came in 1852 that concerned the work of Gabriel Lamé for the application and invention of curvilinear coordinates. In 1872, Enrico Betti proposed the reciprocal theorem. Valentino Cerruti in 1882 applied this theorem to plane boundary solids. The same problem was treated by other methods by the likes of Joseph Valentin Boussinesq, Lamé, and Clapeyron. Further support came through notable contributions from Lamé's study on strained spheres in 1854, the treatment of flexed plates in 1850 by Kirchhoff, treatment of oscillating systems with finite degrees of freedom by Rayleigh in 1873, and Duhamel's (1838), Kelvin's and Neumann's equations on thermoelasticity. Kelvin moreover made some important contributions with his works in 1863 on the elastic spheroids and their geophysical applications as well as with his study of torsion of prisms in 1878.

Dynamics

Joseph-Louis Lagrange's unrivaled feat of reasoning of the 18th century, his *Mecanique Analytique* of 1788, was inherited by the following century's investigators of pure dynamics. Until 1813, the presence of the master played an important part

in watching over the legitimacy of its applications and pointing out its resources. Each new advancement made had gone on to vindicate the preeminent safety and power of its methods. There were successes with the deduction of electromagnetic field kinetics by Maxwell in 1864 and its adaptation to the chemical systems equilibrium by Gibbs. The method of *liasons* faced natural reactions. The most outspoken proponents came under the protection of Laplace, for example, Poisson's *Mecanique Physique* of 1828, an extension of dynamics of Roger Boscovich which permeated the works of such figures as Frensel, Navier, Cauchy, Ampère, Boussinesq, de St. Venant, and others. Cauchy had tried to reconcile molecular methods based on Lagrangian abstractions. Poisson's method proved to be untrustworthy, however, notwithstanding its superiority in the instances of classic elastics and capillarity. The influence of the medium came to the fore with the rise of modern electricity, and Poisson's method was rudely shaken.

Thomson and Peter Tait are credited with a complete revision of dynamics during their endeavor to obtain uniformity and clarity of design by going back to Newton and logically reconstructing the whole field. The principle of conservation of energy was systematically used for the first time in this major work. Going with the contemporary trend, Hertz in 1894 made a strong effort to exclude altogether potential energy and force from the purview of dynamics. He went on to postulate a universe of concealed motions as in Helmholtz's treatment of cyclic systems theory and the idea of a dynamic gyrostatic ether proposed by Kelvin in 1890. In fact, Boltzmann and Helmholtz introduced ordered molecular motions, and concealed systems proved to be highly potent in the justification of Lagrange's dynamics, particularly when applied to actual natural motions.

During the 19th century, first-rank-specific contributions with mathematical difficulties or in the applications of the subjects were very few. The principle of least constraint proposed in 1829 by Carl Friedrich Gauss, although superior to the displacement method in its applications, was seldom used. But it was the development and adaptation of Gottfried Wilhelm Leibniz's (1646–1716) systematic formulation of first principles to the law of conservation of energy that impelled the

progress of the domain of dynamics in the 19th century. Although the writings of Lagrange in 1777 included an explanation of potential, and Laplace in 1782 had already provided the differential equation on which the principle was based, the latter was completed by Poisson only decades later, in 1827. Major contributions came from Gauss with regard to force flux and surface integrals when he proposed his influential theorems in 1813 and subsequently in 1839. In 1854, George Stokes contributed important work on the relation of surface and line integrals. The most prominent of the authors on volume surface and line potential were Michael Chasles, Robert Murphy, Peter G. L. Dirichlet, C. Neumann, and Helmholtz. Gradually, the dynamists of subsequent generations have shown more inclination toward vector calculus and geometry. A significant contribution in this regard was made by August F. Möbius. In addition, William Rowan Hamilton's *quaternions* of 1853 and Hermann Grassmann's *Ausdehnungslehre* ("On Expansion") of 1844 played vital roles. Another work of major significance was Sir Robert Ball's 1876 study of the theory and immediate dynamic applications of screws. Other work with profound experimental aspects include Hippolyte Fizeau's gyrostat and Léon Foucault's pendulum, both of 1851, and the quartz-fiber torsion balance of Charles Vernon Boys (1887) that could measure, with greater precision than any other apparatus, the earth's mean density and Newton's gravitational constant. Some other important work of this period includes George Biddell Airy's pendulum of 1856, Philipp von Jolly's balance methods of 1881, and the contributions of Arthur König and Franz Richarz, published in 1885. The century also saw the beginning of Thomas C. Mendenhall's extensive U.S. transcontinental surveys in 1895.

Hydrodynamics

The extensive labors of Lagrange, Alexis Clairaut, and Colin Maclaurin between 1742 and 1788 made it possible to understand the equilibrium of liquids even with regard to rotating fluids before the beginning of the 19th century; the domain of hydrodynamics thus bequeathed a rich legacy of development. The triaxial ellipsoid of revolution was generalized by Moritz von Jacobi in 1834.

George Howard Darwin (1887) and Henri Poincaré (1885) extended it to two rotating attracting masses. Particular mention should be made about the astonishing revelations in the works of Poincaré. The subject was divided into classes of motion (flow in jet waves, streams, and tubes) possessing velocity potential by Helmholtz in his famous paper of 1858. Thomas Craig and Henry A. Rowland in 1881 carried out the classification for the higher orders of motion. The century saw significant progress in the treatment of waves for cases with velocity potential, dynamics of solids in frictionless liquids, and the treatment of discontinuous fluid motion. Progressive wave motion in shallow vessels was dealt with by Green, Scott Russell, and Philip Kelland, while those for deep water progressive waves were studied by Rankine and František Josef Gerstner. Most of the problems faced in the advancements of hydrodynamics were countered by the analytical works of Stokes. The case of ripples, introduced by Kelvin in 1871, was treated by John William Strutt, Lord Rayleigh, in 1883. The efforts of Dirichlet, Stokes, and Poisson solved the problem of spheres, while the problem of ellipsoids was touched upon by Kirchhoff, Clebsch, and Green. Rankine was successful in his treatment of ellipsoidal and cylindrical translatory motions in a way similar to that of the resistance offered by ships. Bjerknes's results with the hydrodynamic force around spheres including rotational, translatory, oscillating, or pulsating have tremendously enriched the field of hydrodynamics. Other influential work in this domain include Greenhill's treatment of ballistics and Josef Ressel's design of the first successful screw ship propeller. The question on the stability of the motion of fluids has been highlighted considerably by the numerous contributions of Kelvin. The study of vortex motion was approached gradually by the likes of George Stokes, Cauchy, and Lagrange. But it was Helmholtz's integration of the differential equations that made for clear interpretations of the whole matter.

Optics

Prior to the 19th century, valuable contributions by Lagrange, Étienne-Louis Malus, Newton, and Christiaan Huygens led to much progress in geometric optics. Gauss, in 1841, put forward a

paper that remodeled the topic and was generalized subsequently by Ernst Abbe and Möbius. In 1835, George Biddell Airy first pointed out the role of diffraction on geometric optics, which was further developed by Rayleigh and Abbe. One of their major accomplishments is the theory of the rainbow. In 1879, Abbe introduced the apochromatic lens, which offers greater correction of chromatic and spherical aberration than the more common achromatic lenses. Jesse Ramsden and Huyghens's eyepiece, which reduces blurring from aberrations, still served the microscope well; however, successive stages of improvement took place in the objective lens, beginning with the invention of the achromatic objective lens by Joseph Jackson Lister in 1830. A series of developments in geometric optics took place, like J. W. Stephenson's introduction of the principle of immersion (1878), Abbe's homogenous immersion (1879), and the apochromatic objective of Abbe-Zeiss (1886). These microscopes gained significantly from the experiments conducted in the glass factory in Jena, Germany. The photographic objective's guiding principle was introduced by Steinheil between 1865 and 1866. The difficult task of constructing fine refractive telescope lenses for major astronomical observatories was carried out by the firm of Alvan Clark & Sons in Cambridge, MA, founded in 1846; many of these telescopes are still in use.

Newton's work nearly culminated in the achievement of spectrum purity early in the 18th century. Nearly a century later, in 1802, it was William Hyde Wollaston who introduced the concept of slits that enabled the visualization of solar spectrum dark lines. Their origin was carefully mapped by Joseph von Fraunhofer, between 1814 and 1823. The first ever notion about the occurrence of spectral absorption was stressed by David Brewster, who believed the phenomenon to be atmospheric. In 1860, he also published a map of 3,000 spectral absorption lines. The D group of Fraunhofer coincided with the sodium lines; this fact was pointed out by Lèon Foucault in 1849, and thereby, sodium vapor's reversing effect was unraveled. The works of Stewart in 1860 and Angstrom in 1855 were instrumental in describing the parallelism of absorption and emission. However, Kirchhoff and Bunsen in between 1860 and 1861 ultimately described the differences between

the dark lines or fixed bright line spectra and the continuous spectra on which basis spectral analyses are made. Later on, improved observations on the wavelength and distribution of solar spectra were made by Robert Thalén, Angstrom, and William Huggins. A definite advancement was noticed with each of the discoveries of Rowland, such as his solar-spectrum maps and tables of 1887 and 1889, and his summary in 1891 of the sun's elemental composition. Alkaline and other elemental structural spectra were successfully analyzed by Kayser and Runge. In 1874, Rayleigh introduced the modernized version of grating theory, which got extended to the concept of concave grating, particularly through the works of Rowland. Langley's 1883 investigation of the infrared spectrum paralleled Rowland's works on visible spectrum. The extension of the detailed accuracy of the spectrum was brought about by the works of Langley, which superseded the investigations of earlier workers like Fizeau and Foucault. The accuracy of the spectrum got improved to nearly eight times of its visible length. The radiations of hot and incandescent bodies, the lunar and solar spectrum were all precisely specified. Our knowledge of solar activity was highly enriched through the valuable experimental suggestions of Lockyer's 1868 spectroheliograph and Jansen's works and the remarkable success achieved though it by the likes of George Ellery Hale.

Playing a major role in the acceptance of the wave theory of light was the work on interference as framed by Thomas Young in 1802, which advanced the earlier experimental work on colors of thin plates by Newton, Hooke, and Boyle. The colors of mixed plates also were investigated by Young, who was aware that reflection from a denser medium results in the loss of nearly half a wavelength. In 1819, Newton's colors were independently explained by Augustin-Jean Fresnel, a civil engineer, in terms of wave interference. Through the course of this work, he devised his triple mirror, biprism, and double mirror. Albert A. Michelson went on to make crucial advancements to the scope of this device, which became a fundamental tool for research in this field. At the U.S. Naval Observatory in 1877 and 1879, Michelson estimated the speed of light in air and in a vacuum with great accuracy. An entirely new interference phenomenon was introduced by Otto

Weiner in 1890 when he discovered the stationary light wave. In the 1890s, Gabriel Lippmann used a two-step method successfully to reproduce colors in photography, for which he would receive the 1908 Nobel Prize in Physics. Understanding of the broader aspects of interference, such as multiple reflections, was successfully advanced by the works of Airy, Fresnel, and Poisson.

PHYSICS, QUANTUM THEORY

Quantum theory is the branch of physics dealing with the behavior of matter at the atomic and subatomic level. It developed during the period 1900–1930, through problems arising at the intersection of thermodynamics, electromagnetism, and the discovery of atoms, electrons, and radioactivity. It has been an astonishingly wide-ranging and successful scientific theory. It has been tested in experiments on energy scales comparable to the early stages of the universe; it has provided explanations of stellar and cosmological phenomena; it has underpinned advances in materials science and chemistry ranging from the development of semiconductors in computing to biological processes at the cellular level.

Its key characteristic is that properties of atomic and subatomic objects can only occur in, or change by, discrete quantities, the smallest of which is a *quantum*. The consequences of this effect have been extraordinarily wide ranging: Properties can only be measured imprecisely; many combinations of properties cannot be simultaneously measured; systems cannot be prepared with well-defined values for many properties; the results of measurements need to incorporate randomness in their description; and the properties inferred from the outcomes of measurements appear to become properties of the manner of the measurement process as well as properties of the object itself.

Despite its empirical success, quantum theory remains one of the most puzzling of scientific theories and has had a significant impact upon the philosophy of science. The question of how one interprets quantum theory remains debated. It appears to suggest the world is very different from how we might have imagined it: ideas such as nonlocal connections between remote locations; branching multiverses; and whether physics should be understood as attempting to give a description of reality at all, have all been advanced in attempts to understand how it can be that quantum theory correctly describes the way the world works.

This entry traces the development of quantum theory in the early 20th century, continues with a brief characterization of the underlying mathematics, and describes the dual nature of quantum objects as both wave and particle. Next discussed are the uncertainty of assigning values to multiple properties of quantum objects, the ambiguity of measurement in quantum theory, and the nature of nonlocal connections. The entry concludes with an explanation of empirical and realist interpretations of quantum theory.

Historical Development

Quantum theory grew out of developments in late 19th-century physics. The *classical* physics of Newtonian mechanics described particles moving in space under the influence of gravitational, electric, and magnetic fields. A field is a property, defined at every point in space, that describes the force that will act on a body at that location. The unification of the electric and magnetic fields by James Clerk Maxwell (1831–1879), in such a way as to show that light could be identified as a wave in the electromagnetic field, had been a triumph of the Newtonian paradigm.

However, the attempt to apply thermal physics to the electromagnetic field seemed to lead to a problem. If a system was able to interact with the electromagnetic field, all of its heat would be absorbed into increasingly high frequency waves of the electromagnetic field. In 1900, Max Planck suggested the problem could be solved if the energy in the electromagnetic field could only be exchanged with matter in packets of a fixed size: a minimum *quantum* of energy, determined by a new universal constant. This quantity increased with frequency,

so the electromagnetic field would be blocked from absorbing energy at extremely high frequencies.

Albert Einstein, in 1905, showed that this light quantum proposal could also account for a phenomenon known as the *photoelectric effect*. Light shone on a metal can cause electrons to be emitted, as the electrons absorb the energy of the light. This effect ceases if the light is below a threshold frequency, regardless of the intensity of the light. Einstein explained this, in terms of a minimum quantum of energy needed to eject the electron from the metal. Unlike Planck, who only suggested that energy must be *exchanged* in discrete quantities, Einstein suggested that the electromagnetic field, including light, was *composed* of individual particles, or light quanta.

At the same time, the discovery of radioactivity and electron-scattering experiments started to provide evidence for subatomic structure: Atoms seemed to be concentrated heavy nuclei of positive charge surrounded by light, negatively charged electrons. According to the theory of electromagnetism, such structures would be highly unstable and would collapse, with the electron spiraling into the nucleus. In 1913, Niels Bohr showed that if the quantum hypothesis was applied to the angular momentum of electrons orbiting the nucleus, then the electrons could only inhabit fixed orbits, preventing the instability. Not only would this solve the problem but jumps between the stable orbits would absorb and emit light quanta with characteristic frequencies (Balmer lines) that had already been observed in hydrogen.

The synthesis of the two problems came in 1924. Planck and Einstein's hypothesis had suggested that light, previously considered a wavelike entity, showed particle-like properties. Louis de Broglie showed that if matter, previously considered a particle-like entity, had wavelike properties, then Bohr's results could be derived.

Two rival mathematical versions of quantum theory developed to describe this: matrix mechanics was developed by Max Born, Pascual Jordan, and Werner Heisenberg, which tended to emphasize discontinuous quantum jumps between stable states of quantum systems; and wave mechanics, developed by Erwin Schrödinger, which originally attempted to describe all quantum processes as continuous wavelike effects. The reinterpretation of Schrödinger's wave equation in terms of

probabilities, by Born, paved the way for Paul Dirac, in 1930, and John von Neumann, in 1932, to show how the two approaches could be unified as examples of a more general structure, called *Hilbert space*, after the influential mathematician David Hilbert. Mathematically, the structure of quantum theory was essentially finalized. The problem of understanding the picture it gave of the world remained.

The Mathematical Structure of Quantum Theory

In classical Newtonian physics, the mathematical structures used are often understood as modeling the way the world actually is. The state of a system is just the list of all the physical properties possessed by the system, and the dynamics describe how those properties change over time.

When describing a system using quantum theory, the quantization process starts with a classical model for a system, then replaces the mathematics with equivalent structures in a Hilbert space. A property is represented by an operator, and a state becomes a vector in the Hilbert space. However, in the mathematical structure to which this leads, the state no longer lists a specific value for each property. Instead, it only gives the probability that the property may have a given value. The dynamics, describing how the state changes in time, gives how those probabilities change in time.

Nevertheless, whenever a property of a quantum object is observed, the observed property will have a well-defined value. Unlike in classical physics, therefore, the quantum state does not seem to be a mathematical representation of the way the world is. Instead it only gives the probabilities of what can be observed, if an observation is made. For this reason, the properties of quantum theory are typically referred to as *observables*, emphasizing the fact that they represent the outcomes of observations, rather than properties of the object itself.

The mathematical structures of quantum observables are very different from classical properties: There are strong limitations on the extent to which quantum properties can be observed, and on which quantum properties can be observed simultaneously. Quantum objects at remote locations seem to show instantaneous influences on each other's properties. The question remains as to whether

quantum objects can possess properties, and of what kind, when they are not being observed.

In prequantum physics, the mathematical description of physical theories seemed to naturally represent physical processes. They came equipped with a picture of the way the world could be, that seemed to explain why the mathematics was successful at making predictions. The mathematics of quantum theory does not appear to provide such an explanation, and providing this is the task of interpreting quantum theory.

Wave–Particle Duality

Quantum objects, whether as electromagnetic fields or as electrons, show both wavelike and particle-like properties, depending upon how they are observed. Experiments using beam splitters can be used to show these properties.

A beam, of particles or waves, passes through a splitter, which deflects half the beam into a second path. The split beams are then reflected and recombined into a single beam. Detectors can be placed into the paths of the beams, to measure the intensity of the beam in any given location.

When the beam is made of particles, and the intensity is reduced to a very low level, the detectors will start to register individual particles. They can track which path the individual particles take, and the detectors will register a particle taking one path or the other, but not both. The intensity of the recombined beam is always equal to the sum of the intensities from the two split beams.

When the beam is a wave, like a water wave being driven down a narrow channel, detectors placed in the two paths will continue to register waves occurring in both channels, regardless of how much the intensity of the wave is reduced. When the beams are recombined, waves can exhibit interference: The intensity of the recombined beam does not necessarily add up to the sum of the intensities of the two split beams. Where the intensity increases, it is called *constructive interference*, and when it decreases it is *destructive interference*. The nature of the interference can depend upon interactions with the waves in both channels.

When a quantum beam is split into two different paths and recombined, constructive and destructive interference can occur in the intensity of the recombined beam. The scale of this interference depends

upon interactions in both paths. This is a signature of waves traveling down both paths. However, when detectors are placed in both paths, at low intensities individual quantum objects are detected in one path or the other. This is a signature of a particle, traveling down only one path.

When the particle-like direction taken by a quantum object is detected, the wavelike interference effects disappear from the recombined beams. Paradoxically, if the detectors are removed from the split beams but the intensity is still kept at the very low level, where it seems individual quantum particles must be following one path or another, wavelike interference effects reappear in the intensity of the recombined beam. It seems as if the quantum object behaves as a particle when observing for particles and as a wave when observing for waves.

Quantum Uncertainty

In classical physics, objects were assumed to have well-defined values for all their fundamental properties, such as mass, electric charge, and so forth. In principle, these properties could all have been simultaneously measured and observed to have well-defined values.

In general, a quantum state only describes probabilities of observing values on measurement. In some cases, though, a quantum state gives a probability of one to a particular result, and then the property does have a well-defined value. In particular, if a property has been observed to have a particular value, the quantum state must change, to reflect the observed value.

However, some combinations of quantum observables cannot be simultaneously assigned well-defined values. The paradigmatic example is the position and momentum of an object. There are no quantum states that can give a well-defined value to both properties. In general, these complementary observables will have a minimum joint uncertainty, so that when one is very likely to be found within a narrow range of values, the other will have a very large spread of possible values. When an observable is measured, and the quantum state changes to reflect the observed value, the new state must introduce a large uncertainty in the value of any complementary observable.

The naive view of this joint uncertainty, much discussed in the development of quantum theory, was that the measurement process, needing to exchange a minimum quantum when interacting with the system, introduces a random disturbance to the complementary properties.

However, the joint uncertainty can be seen without introducing such measurement disturbance. Suppose a collection of quantum objects are prepared in the same quantum state. Half are randomly selected for observation of one property, and half have the complementary property observed. None of the objects is subjected to both measurements. Nevertheless, the spread in values over the two sets still shows the joint uncertainty: If the first group reveals only a narrow range of values, the second group must show a wide spread in the complementary property, and vice versa. The joint uncertainty is already present in the quantum state, before measurement takes place.

The Measurement Problem

The quantum state doesn't attribute definite values to properties. Quantum objects are only described by the probabilities that values will be observed when measured. However, quantum theory leaves ambiguous what constitutes a measurement.

A measurement process involves a quantum object interacting with a much larger device, which records the outcome. Typically, the measuring device will be a much larger system, amplifying the outcome up to a level that is directly observable, such as numbers printed on paper or a screen.

The measuring device itself, however, is built up out of atoms and their interactions, so presumably quantum theory should also apply to the measuring device itself. This leads to a problem: when the measuring device is also described by quantum formalism, it does not attribute definite values to the measuring device either, including not giving a definite value for the outcome of the experiment itself. Most problematically, the quantum state seems to allow the possibility of constructive and destructive interference effects between the different possible outcomes of the measurement. This is characteristic of wavelike properties and seems incompatible with the idea that the measuring device really has recorded one outcome or another. The quantum formalism only gives a probability

that the measuring device will show a given outcome when the device itself is measured. Attempting to measure this device with another measuring device only shifts the problem on, as trying to describe the new device using the quantum formalism raises exactly the same issues.

Real measuring devices show a statistical mixture of definite outcomes, which cannot, even in principle, exhibit interference. The difference between the quantum state—which describes no particular outcome and maintains the possibility of interference—and the statistical mixture of outcomes has been described as the “collapse of the wavefunction.” The single quantum state collapses onto a probability distribution over quantum states, each one representing a different possible outcome. The problem for quantum theory is that no process within the quantum formalism can rigorously describe such a collapse.

Quantum Nonlocality

Recall that in the beam splitter the atom appears to go down one path, while still being affected by interactions in the other path. Although this seems paradoxical, there is no detectable evidence that interactions in one path are having an immediate influence in the other path: the observable results only appear when the beams are recombined. If there were instantaneous influences, then this would be a significant problem for the theory of relativity, which forbids such influences.

When two quantum objects are allowed to interact and separate, however, the situation becomes more problematical. In 1935, Albert Einstein, Boris Podolsky, and Nathan Rosen argued that strongly correlated quantum objects must either use instantaneous influences, or else the objects must actually have definite values for their properties even though the quantum state does not describe them.

A strongly correlated (known as *entangled*) quantum state of two objects can ascribe a definite value to the joint properties of the system, such as the sum of their momentum, without ascribing a definite value to the individual properties of the subsystems, such as the individual momentum. If the objects are widely separated, and the momentum of one object is measured, it will acquire a definite value. However, the second object also

must acquire a definite value of momentum, as the sum of the two remains fixed.

Either the value of the second momentum was *already* definite prior to the measurement occurring, or its value was *made* definite by that remote measurement. The first possibility means that the second object must have had a definite momentum, even though the quantum state did not describe it. The second option implies the measurement had an instantaneous influence on a remote location.

Problematically for Einstein and colleagues' argument, in 1964 John Bell was able to show that the correlations between remote quantum objects could not be explained without instantaneous influences. Einstein had sought an explanation for the correlations between the remote objects entirely in terms of the existence of properties prior to the remote measurements being performed. Bell showed that this implied a limitation on how well the two objects could show correlations for combinations of different measurements. Entangled quantum states are able to exceed this limitation. The conclusion would appear to be that measurements can create or influence properties at remote locations, regardless of the conflict with relativity theory.

Empiricist Interpretations of Quantum Theory

Empiricist approaches to the problem of interpreting quantum theory focus upon the mathematics of quantum theory as a tool for making predictions and suggest that is all a good scientific theory should aspire to. Further questions about what might be happening when a system is not being observed are regarded as pseudoproblems, without empirical content.

The Copenhagen interpretation, as it is known, was the first such approach, which was actually a number of distinct ideas associated with Bohr and Heisenberg. It was strongly influenced by positivism, and by ideas that it was meaningless to attribute values to quantities that are not directly measured or observed. It came to dominate the interpretation of quantum theory for several generations.

A key element was Bohr's analysis of the process of measuring objects at the atomic level. Because atomic objects cannot be directly observed,

this always requires some amplification process, to bring the result up to a level where a classical description becomes valid. The interaction between classically describable experimental devices and an atomic object necessarily involves an exchange of discrete quanta. When the interacting systems are both large, the scale of this interaction can be treated as negligible with respect to the properties being observed. As the system of interest became smaller, the minimum quantum of interaction between the systems means that it was no longer possible to treat the interaction of the measuring device with the system as negligible. The phenomenon that emerges in the measuring device is a property of the whole arrangement of system and measuring device and cannot be attributed solely to the quantum object; Bohr argued that attempts to do so lead to paradoxical properties, as exemplified by wave-particle duality. Bohr's position emphasized the holistic aspect of the process, so that particle-like phenomena are properties of experiments for particle-like properties, and wave-like phenomena are properties of experiments for wavelike properties, associated with two different types of experimental apparatus. The paradox, to Bohr, only seems to arise if one tries to attribute the wavelike or particle-like properties to the quantum object itself, independently of the means used to measure it.

This position does not necessarily deny the existence of quantum objects or that they may possess properties, but it does not regard the properties predicted by quantum theory as pertaining to the quantum objects alone. Quantum theory can only discuss the properties of experimental arrangements, without further analysis into properties of subsystems.

This position dissolves the measurement problem by suggesting it was a mistake to apply the quantum formalism to the measuring device. The existence of the directly observable, experimental device has to be taken for granted. The quantum formalism is not a description of the properties of quantum objects but instead is a tool for predicting the behavior of the experimental apparatus when its interactions are sensitive to the individual quanta exchanged between systems.

Quantum Bayesianism is an example of a modern empiricist interpretation. This holds, broadly, that quantum theory is a form of inferential

reasoning, generalizing classical Bayesian probability theory. As a Bayesian theory of probability, it takes the view that the probabilistic statements quantum theory makes are strictly the degrees of beliefs, exemplified by gambling commitments, of rational agents, as to the outcomes of their observations.

The empiricist point of view is compatible with a number of different attitudes to the existence of quantum objects and their properties: They may exist, but it is impossible to describe them, or meaningless to talk about them or analyze their properties; or it is incoherent to hold beliefs about their properties that go beyond beliefs about the empirical predictions one can make about the results of interactions with quantum objects. The most radical claims, that there is no world independent of our interactions with it, moves away from empiricism and into skepticism or solipsism.

Realist Interpretations of Quantum Theory

Realist approaches to quantum theory accept the same empirical content of quantum theory as the empiricist but believe it is still fruitful to ask how the world could be so that quantum theory holds. Three broad perspectives have developed within this.

The first point of view attempts to understand the mathematical formalism of quantum theory as a literally true description of the way the world is, without addition or modification. The most immediate challenge to this is that of accounting for the measurement problem, where the application of quantum theory to the measuring devices themselves does not appear to lead to outcomes with definite values. The solution, first suggested by Hugh Everett in 1957, was the radical idea that all the possible outcomes do, in fact, occur (possible according to the predictions of quantum theory, as opposed to logically possible or conceivably possible). The wavefunction does not collapse. Instead, when the measuring apparatus seems to ascribe no definite value to the outcome, its quantum state is interpreted as describing several noninteracting copies of the system, each one exhibiting one of the different outcomes. When another system observes this device, the second system also branches into noninteracting copies, each now observing the outcome on a single copy of the device.

This approach has become widely known as the Many Worlds interpretation of quantum theory. For a while, it encountered considerable technical difficulties in accounting for the probabilistic predictions of quantum theory, but recent developments have, according to advocates of this point of view, answered these problems. Despite its apparent fantastic explanation, it remains in some respects the most conservative point of view, as it adheres most closely to the mathematical formalism of quantum theory.

The second point of view approaches the measurement problem by suggesting that there must be additional properties in the world. When the measuring device is described by a quantum state that does not give a definite value to the outcome of the experiment, and yet the observed fact is that the measuring device does give one out of a number of definite values for a property, this point of view holds that there must be facts in the world in addition to those given definite values by quantum theory. These additional facts have been termed *hidden variables*.

The most developed interpretation of quantum theory following a hidden-variable approach is the de Broglie–Bohm theory, first propounded by de Broglie, and independently rediscovered by David Bohm in 1952. In its most basic form, it attributes to atomic objects a well-defined position, in addition to a quantum state. The quantum state evolves in the manner of a wave, giving the interference and wavelike properties, while the position is guided by the quantum state. In this way, it answers the wave–particle duality problem by suggesting, not *wave or particle* but *wave and particle*. The measurement problem is solved by the additional position variable picking out which outcome has actually occurred, avoiding the need to postulate all outcomes actually occurring. The de Broglie–Bohm theory shares with the Many Worlds theory the idea that the quantum state is a representation of real physical properties. Advocates of Many Worlds have argued the de Broglie–Bohm interpretation is therefore also committed to the belief in the physical existence of the other worlds.

An alternate, if less well developed, approach to hidden variables asserts that only the hidden variables themselves, and not the quantum state, represent physically real properties. This is often

called “ Ψ -epistemic,” as it regards the quantum state (traditionally represented by the Greek character Ψ [psi]) as representing only epistemic uncertainty as to the actual state of the world. What distinguishes this from empiricist approaches is the idea that not only are there objective properties to the world, but that these properties can be meaningfully discussed and analyzed. The empiricist regards the quantum state as epistemic uncertainty about future measurement outcomes. The Ψ -epistemicist regards the quantum state as epistemic uncertainty about the state of the world.

The third point of view solves the measurement problem by proposing that quantum theory applies well to atomic objects, but that the dynamics of quantum theory must be modified to apply to large objects consisting of a great many atoms. The collapse of the wavefunction occurs through a physical process that differs from the normal quantum evolution. This is often known as an objective, or dynamical, collapse.

This novel process must be sufficiently slow that atomic objects still display quantum interference effects on the timescales that have been observed, while aggregate objects lose quantum interference effects and become essentially classical by the time they are directly observable. The two most developed proposals for this are the Ghirardi-Rimini-Weber and continuous spontaneous localization models. A characteristic feature of these approaches is that they must make experimental predictions that deviate from quantum theory at some point.

PHYSICS, RENAISSANCE

Historians generally date the period of European history known as the *Renaissance* (French for *rebirth*) from the mid-14th century C.E. through the 15th and 16th centuries, beginning in Italy with the revival of learning from classical antiquity, and later spreading throughout Europe, aided by the invention of the movable-type printing press by the German craftsman Johannes Gutenberg around 1440. The Republic of Florence, Italy, is commonly thought to be the birthplace of the Renaissance, owing to its political structure, its civic and social peculiarities, the patronage of the Medici (its dominant family) and the migration of Greek scholars and their texts to Florence following the Ottoman Turks’ conquest of Constantinople, the capital of the Byzantine Empire, in 1453.

The Renaissance was a time of great social and cultural change that was felt in politics and religion, in art and architecture, music, philosophy, and the natural sciences. In the literature, authors began increasingly to write not in Latin but in native (vernacular) European languages. Renaissance artists studied how to depict objects in the same way they are perceived by the human eye, according to principles of perspective. Voyages of exploration over land and sea led to greater contact with other cultures and the spread of ideas. During the Middle Ages, understanding of the physical world had relied on beliefs in the supernatural, and it was thought the nature of the universe could not be explained by systematic observation and

experimentation. Renaissance thinkers changed this view with the radical concept that the universe could be studied and approached objectively. Mathematicians discovered that certain mathematical relationships were embodied in the natural world. The era's intellectual transformation acted as a bridge between the Middle Ages and the Modern Era. This entry focuses on the major developments in the domain of physics and related disciplines based on direct observation, such as astronomy and the study of magnetism; and the work of such key figures as Nicolaus Copernicus, Galileo Galilei, Johannes Kepler, and William Gilbert.

Astronomy and Physics

During the Renaissance period, the fields of astronomy and physics shared much common ground, and many theories by physicists sought to explain cosmological phenomena.

In modern science, there is still much overlap between astronomy and physics, as physicists use the universe as their *laboratory* for testing theories through observation. Astrophysicists and cosmologists study phenomena such as the effects of gravitational lensing and use increasingly powerful telescopes in an ongoing effort to understand the origins and nature of the universe. These observational practices were pursued without the aid of optical instruments by—most notably—the ancient Greeks, Babylonians, Aztecs, and Mayas, among others, and have been refined through the course of history, including the Renaissance period, when scholars such as Nicolaus Copernicus and Galileo Galilei used astronomical observations to propose theories to explain the universe's principles of motion.

Copernicus

Nicolaus Copernicus (Mikolaj Kopernik), who lived from 1473 to 1543, blended cosmology, mathematics, and physics in an effort to design a model of the universe. Born in Poland to a family of wealthy merchants, he studied liberal arts at the University of Krakow and traveled to Italy for further education preparing for a future in canon law. He studied astrology there as well as astronomy. Today, of course, astronomy is taken much more seriously in the scientific community than is astrology.

While attending the University of Bologna, Copernicus worked and lived with astronomy professor Domenico Maria de Novara, whom he helped make observations of the heavens. When he returned to Poland after graduation, one of the rooms in a large tower in his town held an observatory, which gave him opportunity to study the night sky. Copernicus never became a priest, but he continued to work as a cleric.

In 1514, Copernicus created a handwritten book for his friends that stated his views on the universe. In it, he argued that earth was not the center of the universe, but that the sun was very close to the center. He also stated that the planet's rotation was responsible for the movement of the sun and stars, as well as changes in the seasons.

Copernicus proposed several revolutionary ideas about around the structure of the solar system and where the earth was positioned in the heavens. Copernicus's ideas were based on astronomical observations gathered over several millennia. What had hitherto been lacking was a coherent theory explaining why certain objects acted in particular ways.

Copernicus proposed that the planets revolve around the sun, and he, like the Greek philosopher, mathematician, and geographer Ptolemy, who had lived and worked in Alexandria during the 2nd century C.E., believed that their orbits were circular and required epicycles. Copernicus's ideas took time to be accepted, because they conflicted with Church doctrine, based on biblical scripture, that the earth was the center of the universe. His views still assumed, however, that the universe reflected a divine, harmonious model composed of perfect circles and spheres, without disorder or eccentricity. During the Renaissance, God's perfection was a central tenet of orthodox belief; to doubt it constituted heresy, and this would not begin to change until Galileo's struggles with Church doctrine during the following century.

At the age of 70, in the year of his death (1543), Copernicus published *De Revolutionibus Orbium Coelestium* (*On the Revolutions of the Heavenly Spheres*). In this book, he finally laid out his theory that the planets orbited the sun rather than the earth, as well as his model of the solar system and the path of the planets, which today we call the heliocentric or Copernican model.

Galileo

Galileo Galilei was born on February 15, 1564, in Pisa, Italy. He was the first of six children born to his father, Vincenzo, a well-known music theorist and musician, and Giulia Ammannati. The family moved to Florence in 1574, and Galileo began attending school at the Camaldolese monastery in Vallombrosa.

In 1583, Galileo enrolled at the University of Pisa to study medicine. With his talent and intelligence, he became entranced with several subjects, including physics and mathematics. The university taught according to an Aristotelian view, which was sanctioned by the Roman Catholic Church, and initially Galileo adhered to this viewpoint. Owing to financial difficulties, however, he left the university before completing his degree.

After exiting the university, Galileo continued to study mathematics, and he supported himself with minor teaching positions. He also began his study of objects in motion, which would last two decades. He published *The Little Balance*, which earned him some attention with his descriptions of the hydrostatic principles of weighing small quantities. His work then gained him a teaching job at the University of Pisa, but his criticisms of Aristotle left him isolated among his peers, and in 1592, his contract with the University of Pisa was not renewed.

This would not be the end of Galileo's teaching career, however. He found a new position teaching astronomy, geometry, and mechanics at the University of Padua. Having been entrusted with the care of his younger brother Michelangelo following their father's death, this appointment came at a fortunate time. Galileo stayed at Padua for 18 years, giving lectures and attracting followers from across Europe. This increased his fame and his desire to fulfill what he saw as his life's mission.

Galileo began gathering evidence that supported Copernican theory and contradicted Church doctrine and the teachings of Aristotle. In 1612, he published his work *Discourse on Bodies in Water*, which refuted Aristotle's ideas of why objects float in water, arguing that was because of the weight of the object in relation to the water displaced, not because of its flat shape.

The next year, Galileo published his work on sunspots, in which he observed and refuted

Aristotle's work that argued the sun was perfect. The same year, he wrote a letter to a student, stating that Copernican theory was not in opposition to Biblical passages. His argument was that scripture was written from an earthly perspective and that science was unique and more accurate in its approach. The letter became public knowledge, and Galileo was labeled a heretic.

By 1616, Galileo was ordered by Church officials not to "hold, teach, or defend in any manner" the Copernican theory regarding the motion of the earth. Galileo obeyed this order a long seven years because of his devout faith and because of his social reputation.

In 1623, one of Galileo's friends (Cardinal Maffeo Barberini) became Pope Urban VIII. He allowed Galileo to resume his studies in astronomy and even publish this work, but only if it was written objectively and did not present the Copernican theory as an undeniable truth.

In 1632, Galileo published the *Dialogue Concerning the Two Chief World Systems*, a discussion among three people: one who argues against Copernicus's heliocentric theory of the universe, one who supports it, and one who is impartial. Though Galileo claimed *Dialogues* was neutral, it was clearly not. The advocate of Aristotelian belief did not give an intelligent argument, and it was clear where Galileo's beliefs stood.

When Galileo invented his telescope, it changed the idea of perfection, as well as showed that a Copernican model of the universe was (albeit incomplete) much more accurate than any other previous models. For the first time, people looking through Galileo's telescope could see that the universe had deep imperfections. Galileo discovered that the moon had mountains and that it looked similar to earth. He also saw that Jupiter had its own moons revolving around it, which astronomers everywhere were shocked to hear. Galileo's work in astronomy was highly controversial, his work in physics was even more so.

Galileo is still known for his groundbreaking work in mass and gravity, though the story of his dropping objects from the Leaning Tower of Pisa is likely a fabrication. Galileo's theories and experimentation showed that a larger or heavy object did not fall to the ground more quickly than a lighter or small object. His work was based on the study of earlier Greek and Islamic

mathematicians, but he gathered all of these data and expanded it, developing a theory to explain how the universe worked.

Galileo's additional contributions included those revolving around the idea of force. Aristotle had showed that the velocity of an object depended on the external forces acting upon it, and in this assumption he was correct. Aristotle made no distinction, however, between acceleration and velocity. He believed that objects moved due to his theory of the four elements (earth, wind, water, and fire) and that each element tried to return to its natural state. A rock, for its part, falls quickly because it is seeking to return to the earth; a feather, by contrast, falls slowly because it is also of the air. It remained to be demonstrated until after Galileo's lifetime that it is air resistance that causes a feather to fall more slowly than a rock; in a vacuum they will fall at similar speeds.

Galileo did not stop there. He expanded his theory to show that an object with no external force pushing or pulling it would maintain a constant velocity, but external forces could cause deceleration or acceleration. This *law of inertia*, so called, which stated that an object would move at a consistent velocity until another force acts upon it, is still accepted as a first principle of physics today. Much of the work Galileo performed depended on his observation of pendula, but he worked with falling objects as well. He would not simply take objects to the top of a tall structure and drop them (without a way to control the variable), because there was no good way to observe and time the fall of these objects.

Galileo built a series of ramps at various inclines that had a smooth channel down which he could roll perfectly smooth balls. In these experiments, he discovered that it was the distance the object fell, not the weight, which was most important. Objects accelerated the further they fell, but weight did not affect this, and all objects accelerated at the same speed.

These experiments were an excellent example of the scientific method. Galileo used deduction and induction to create his experiments and gather results and conclusions. This earned Galileo the reputation of the father of experimental science for many scholars, though this can, of course, be debated.

Reaction by the Church

The Church's reactions to Galileo's publications was quick, and he was summoned to Rome for a trial. The Inquisition lasted about 10 months, and he was treated with respect and never imprisoned. In an attempt to break his spirit once and for all, however, Galileo was threatened with torture, and he was forced to admit that he had supported Copernican theory, but kept his theories that Copernicus's statements were correct to himself.

Galileo was convicted of heresy, which led him to spend the latter years of his life under house arrest. Though he was ordered not to have any visitors or have his any further works printed outside of Italy, he ignored both of these warnings. A French translation of his work was adopted, and a year later, copies of his work called *Dialogue* were printed in Holland. While under house arrest, Galileo did not remain idle. Instead, he wrote a summary of his life's work on the strength of materials and science of motion. This work was called *Two New Sciences* and was published in Holland in 1683. Galileo was ill and blind by this time, and he eventually died after suffering from a fever and heart palpitations. The Church, at the time, still did not accept his work.

Galileo's Legacy

In 1758, the Church lifted the ban on many of the works that supported Copernican theory, and in 1835, it accepted that heliocentrism was a correct model, altogether. By the 1900s, many successive popes had acknowledged Galileo's great works, and in 1992, Pope John Paul II expressed his regret about how the Church had handled Galileo's work and treated him personally.

Galileo made major contributions to our understanding of the universe, and his methods of making his discoveries are just as important as his findings. Given his significant role in the scientific revolution, he is often called the *father of modern science*.

Kepler

Johannes Kepler, who lived from 1571 to 1630, was a German astronomer who discovered the

three major laws of planetary motion. They are as follows:

1. The planets move in elliptical orbits with the sun at one focus.
2. The time taken to traverse any arc of a planetary orbit is proportional to the area of the sector between the arc and the central body (*area law*).
3. There is an exact relationship between the cubes of the radii of planets' orbits and the planets' periodic times (the *harmonic law*).

Kepler himself did not refer to these findings as *laws*. That would happen when Isaac Newton later derived them from a new, unique set of general physical principles. Newton believed that these laws were celestial harmonies that reflected God's greater design for the universe.

Kepler's discovery differed from Copernicus's heliocentric model in that it showed a dynamic universe, with the sun actively pushing the planets in noncircular orbits. Kepler's physical astronomy theories created a new problem for other important 17th-century thinkers to solve—including Newton.

In addition to his work with the solar system, Kepler made additional efforts to provide a new account of how vision occurs. He developed a unique explanation for how light behaves in the newly invented telescope, and he discovered several new, semi-regular polyhedrons. He even offered a new theoretical foundation for astrology, while restricting its ability to be taken as fact.

Kepler studied many different fields, and his unique approach inspired those after him to make further discoveries, reflecting the efforts of scholars in different disciplines working in tandem. Though Kepler was most interested in studying astronomy, during his time this field was taught as a mixed science that consisted of a physical and mathematical component, having elements in common with other studies, such as optics and music. It was divided into practical and theoretical categories, including theory and practical construction of planetary instruments and tables.

In the 16th century, there was no true *scientific community* to speak of. Schooling in Germany (where Kepler lived) and throughout the entirety of Europe was controlled by the Church (whether Catholic or Protestant). Local rulers used these

educational centers to consolidate the loyalty of their populations. One way they did so was by giving out scholarships to poor boys, who, feeling fortunate and blessed to receive an education, would be loyal to the local ruler throughout their lives.

Kepler was from a modest family in the town of Weil de Stadt, and he was one of the beneficiaries of these ducal scholarships. He attended the Lutheran *Stift*, or seminary, at the University of Tübingen, where he began to study in 1589. Boys who attended these schools were expected to become state functionaries, ministers, or schoolteachers. Kepler had planned on becoming a theologian.

Kepler's life did not turn out quite as he expected it would. He believed that Divine Providence led him to study the stars, and he believed that this was a religious vocation. Kepler studied under mathematics professor Michael Maestlin, one of the most advanced astronomers in his country. A former Lutheran pastor, he was one of the few people who adhered to the Copernican theory of the late 16th century, but he was shy about saying so in person or in print.

Maestlin lent Kepler his annotated copy of *De revolutionibus orbium coelestium libri VI* (*Six Books Concerning the Revolutions of the Heavenly Orbs*), written by Copernicus. Kepler found himself extremely attracted to this work, and Maestlin tutored him on its finer details. Kepler believed Copernicus's work was a revelation; it clearly showed the mark of divine planning. Kepler made it his mission to demonstrate what Copernicus had merely guessed, and he presented his explanations in philosophical and religious vocabulary.

Kepler was not the only scientist to believe that the earth/nature had a spiritual connection. His ideas differed, however, in the intensity with which he believed them. For example, he was very strongly attracted to the idea that the Christian Trinity was symbolized by a geometric sphere, and therefore, the visible, created world was a reflection of God's divine mystery. One of Kepler's favorite Biblical passages was as follows: "And the Word became flesh and lived among us" (John 1:14).

For Kepler, this meant that the divine archetypes were made visible as straight and curved forms that became the spatial arrangement of tangible corporeal entities. Kepler believed that God was a creative, dynamic being whose presence was symbolized by the sun, and whose force

occasionally moved the planet. For him, the natural world was a mirror for divine ideas. Kepler believed that the human mind was created to understand the world's structure, and he believed that the soul was of the utmost importance to one's being.

Kepler's ideas were presented in his first work, *Mysterium cosmographicum* (1596; "Cosmographic Mystery"), and he continued to work with these same ideas and issues throughout his entire life. During 1595, Kepler had a moment of illumination while teaching a small class in Austria. He realized that the spacing between the six Copernican planets could be explained by inscribing and circumscribing each orbit with one of the five regular polyhedrons. Kepler recognized Euclid's proof that there can only be five such mathematical objects composed of congruent faces, and he decided that this self-sufficiency must come with a perfect idea. He thought that if the ratios of the mean orbital distances were in agreement with the ratios obtained from inscribing and circumscribing the polyhedrons, then he could discover the architecture of the universe. Kepler did find agreement within 5%; his exception was Jupiter.

Magnetism

Gilbert

William Gilbert, who lived from 1544 to 1603, was an English physician who also studied electricity and magnetism, though he did not fully understand the complexity or exact principles of either of these fields. Gilbert studied at Cambridge University and became a renowned doctor shortly afterwards. At university, Gilbert studied compasses and magnets, which were essential in England, a seafaring nation.

Magnets, which are known for their properties of attraction and are also known as lodestones, were well known to the Greeks and Muslims, as well as sailors across the globe. However, none of these groups understood the exact reasons that compasses work. Many scholars thought that they were simply attracted to the North Star or a collection of magnetic mountains somewhere within the Arctic Circle.

William Gilbert was not satisfied with this type of reasoning, and he set out to do a number of experiments on magnets. He came to understand some of the properties of magnets by using a large, spherical lodestone and a compass needle that

could rotate freely. Gilbert found that magnets lose their power of attraction when exposed to high temperatures; that they often produce circular motions; and that rubbing certain metals with magnets also turns them magnetic.

Gilbert realized that magnetism and rotation were often linked, which led him to suggest that the earth was one large magnet—an idea that he explained in his work *De Magnete* in 1600. In this work, Gilbert also rejected the idea that the earth was central to the universe and instead proposed that the earth was a giant magnet with north and south poles that was part of a heliocentric model.

Gilbert's work was thought by his contemporaries to be a breakthrough, and it would go on to influence Galileo's views of the structure of the universe. His experimental method was also revolutionary, in that it may have been the first example of an experimental scientific method. In addition, Gilbert's work on a concept he called *electricity* would create a foundation for scientific thinkers long afterward, but especially during the Enlightenment.

PHYSICS, SOLID-STATE

Solid-state physics is defined as the study of solids of rigid matter, through various methods such as crystallography, metallurgy, electromagnetism,

and quantum mechanics. Solid-state physics explains the different properties of all solid materials and the properties of a collection of atomic nuclei and electrons interacting with electrostatic forces among themselves. It also typically formulates the basic and fundamental laws that govern the typical behavior of solids.

Since the 1960s, this branch of physics has been subsumed by more general category of *condensed matter physics*. This was done mostly to include fluids, which also in many cases readily share the same concepts and analytical techniques as those of solids. Thus, solid-state physics is now commonly discussed under the more comprehensive term, *condensed matter physics*, of which it is generally considered to be the largest branch. Condensed matter physics is actually the field of physics which deals with both the microscopic and macroscopic physical properties that matters possess. In particular, it is chiefly concerned with the extensive “condensed” phases that, in most cases, appear whenever the probable number of participating constituents in a particular system is quite large and the typical interactions between these constituents are fairly strong. The most familiar and examples of the condensed phases are of course solids and liquids, which typically arise from the strong electromagnetic forces that exist between atoms. Solid-state physics is concerned with studies that explain how large-scale properties of relatively solid materials actually result from their intrinsic atomic-scale properties. Thus, it can be estimated that solid-state physics forms the appropriate theoretical basis of the vast application-based field of *materials science*. It also has some direct applications, as for example in relation to the hardcore technologies concerning semiconductors and transistors. Solid materials, as we know, are typically formed from densely packed atoms. These atoms interact intensely among themselves. These sophisticated interactions mostly produce the specific mechanical (e.g., elasticity and hardness), magnetic, thermal, optical, and electrical properties of solids. Depending on the type and kind of material involved and the relative conditions within which it was actually formed, the atoms may constitutively be arranged in a specific regular, typical geometric pattern (like crystalline solids, which mainly include all the metals and ordinary water or ice) or quite

irregularly (e.g., a grossly amorphous solid such as common window glass).

Crystals and Crystallography

The bulk of solid-state physics, viewed mostly as general theory, is extensively focused on crystals. Crystalline materials are solids with a highly organized atomic structure typically based on a regular repeated pattern. Most solids that are known happen to be crystalline. There are also some known liquid crystalline colloids of the nanoparticles. Much more progress has been effectively made in first decades of the 21st century to understand the behavior of these crystalline solids rather than that of the noncrystalline materials, since most of the concerned calculations are easier to perform on crystalline materials. Understanding the basic electrical properties of these solids is of pivotal importance to modern-day society and advancing technology.

Primarily, this phenomenon is because of the periodicity exhibited by the atoms in a crystal—its defining characteristic, which greatly facilitates mathematical modeling. Similarly, crystalline materials quite often have magnetic, electrical, mechanical, or optical properties which can be exploited for the purposes of engineering. The typical forces that exist between the constituent atoms in a crystal can take a variety of structural forms. For example, a crystal of sodium chloride (i.e., common salt) is basically made up of sodium and chloride ions, which are held together with many ionic bonds. Sodium chloride specifically crystallizes in the form of a cubic lattice, but with a very different unit cell. The structure of sodium chloride consists of exactly equal numbers of both sodium and chlorine ions, stringently placed at every alternate point of a very simple cubic lattice. In contrast, the noble gases (helium, neon, argon, krypton, xenon, and the radioactive radon) never undergo any of these typical types of bonding. In solid form, all the noble gases are actually held together with the Van der Waals forces acting between them, resulting from the total polarization of the surrounding electronic charge cloud on each of these atoms. The actual difference that exists between the types of solid typically result from the fundamental differences between their intimate bonding. Many properties of these solid

materials are vastly affected by their crystal structure. This structure can be effectively investigated using a wide range of various crystallographic techniques including neutron diffraction, X-ray crystallography, and electron diffraction. Various diffraction techniques solely exploit the phenomenon of scattering of radiation from a large number of available sites. There are various diffraction techniques which are currently being employed that result in typical diffraction patterns. These typical patterns are gross records of the various diffracted beams produced. The sizes of individual crystals found inside a crystalline solid material do vary extensively depending on the type of material involved and the prevalent conditions when the material was formed. Most of the crystalline materials encountered in everyday life are by nature polycrystalline, with the individual crystals being microscopic in scale, but macroscopic single crystals can also be very easily produced either by natural (e.g., diamonds) or artificial methods.

A single crystal has a typical periodic atomic structure almost across its entire volume. At long-range typical-length scales, nearly every atom is generally related to almost every other grossly equivalent atom in the utmost structure by rotational or translational symmetry. These polycrystalline materials are mostly made up of clusters of many tiny single crystals (called *grains* or *crystallites*). Polycrystalline materials have a high degree of restricted order over many molecular or atomic dimensions. Grains (*domains*) are typically separated by the grain boundaries. Their atomic order can greatly vary from one particular domain to the next. The grains are usually 100 nm to 100 μ m in diameter; polycrystals which have grains that are less than 10 nm in diameter are actually nanocrystalline. On the other hand, amorphous or noncrystalline solids are made up of randomly orientated molecules, atoms, or ions that do not necessarily form exactly defined lattice structures or patterns. Amorphous materials range only within a few molecular or atomic dimensions; such materials do not actually have any particular long-range order, but they seem to exhibit varying degrees of short-range order structures. Examples of amorphous materials include the amorphous plastics, silicon, and glass. These amorphous

silicates are readily used in thin-film transistors and solar cells.

Crystallography is a specific branch of science which deals with the basic geometric description of all crystals and the internal arrangement of their atoms. The symmetry of a typical crystal is obviously important for its profound influence on the crystal's general geometric properties. These structures should hence be effectively classified into different types according to the basic symmetries they possess. All energy bands can be distinctly calculated when their structure has well been determined. In the case of elaborate crystallography, when studying a crystal lattice the main interest is in the geometrical properties of the crystal; hence one may suppose replacing each of the atoms by a specific geometrical point located exactly at the typical equilibrium position of that particular atom. Relatedly, there exists an infinite array of points in the space; each point has more or less identical surroundings to all the other points. All these arrays are regularly arranged in a periodic manner. Crystal structures can be obtained by attaching atoms, groups of atoms, or molecules which are called basis (motif) to the lattice sides of the lattice point. The unit cell (group of atoms, ions, or molecules) can be considered the smallest component of the crystal, which when stacked together with pure translational repetition reproduces the whole crystal. Real crystals actually feature irregularities or defects in their ideal arrangements, and it is mostly these defects that critically determine almost all of the mechanical and electrical properties of the real materials.

The crystal lattice has the ability to vibrate. These intense vibrations are typically found to be super quantized; these exceptionally quantized different vibrational modes are known as *phonons*. A phonon is actually a collective excitation which occurs in a periodic arrangement of molecules or atoms in a typical solid and some liquids. Although it is often referred to as a typical quasiparticle, the phonon actually represents a very excited state in the actual mechanical quantization of most of the different modes of vibration of typical elastic structures of rapidly interacting particles. Phonons typically play a major role in many of the physical properties of condensed matter, such as electrical conductivity and thermal conductivity. The study of these phonons is an

important part of contemporary condensed matter physics. The concept of these phonons was first introduced in 1932 by the Russian physicist Igor Tamm. The term *phonon* comes from a Greek word that means anything that translates sound or voice. The phonons of longer wavelength mostly give rise to sound, whereas the shorter wavelength and higher frequency phonons typically give rise to heat. In the insulating solids, phonons are also the main and primary mechanism by which gross heat conduction takes place. Phonons are by far also necessary for critically understanding the exact lattice heat capacity of any solid, as explained in the Einstein model of the solid and later clearly demonstrated by the Debye model, developed by Peter Debye in 1912, for estimating the phonon contribution to the heat capacity of a solid.

Properties of solid materials such as heat capacity and electrical conduction are largely investigated by solid-state physics. The Drude model, proposed in 1900 by the German physicist Paul Drude, was one of the earliest models explaining electrical conduction in solids, which mainly applied the kinetic theory to the free and bound electrons in a solid. By assuming that the solid material actually contains many immobile positive ions and a typical “electron gas” of classical, basically noninteracting electrons, the Drude model was able to clearly explain thermal and electrical conductivity, and the Hall effect in these metals, although the electronic heat capacity is greatly overestimated. Arnold Sommerfeld for the first time combined the classical Drude model with the concepts of quantum mechanics in his established free electron model of 1927 (more frequently called the *Drude–Sommerfeld model*). Here, the free electrons are actually modeled as a typical Fermi gas—in other words, a gas of particles that obey the critical quantum mechanical model relating to Fermi–Dirac statistics. This free electron model actually gave improved predictions about the heat capacity of the metals. The model is actually an almost total modification of the basic electron model that mainly includes a quite typical weak and periodic perturbation, which is basically meant to variably model the basic interaction between the exact conduction of these electrons and the typical ions in a basic crystalline solid. By introducing the new idea of electronic bands, the

theory properly explains the existence of conductors, semiconductors, and insulators. This almost free electron model typically rewrites the Schrödinger equation for the exact case of a periodic potential. The available solutions in this case are better known as *Bloch states* (after the Swiss physicist Felix Bloch). Bloch’s theorem applies only to exact periodic potentials, and these unceasing and random movements of atoms within a crystal disrupt the regular periodicity, but it has actually proved to be a highly valuable form of approximation, without the use of which most of the analysis of solid-state physics would be totally intractable.

Current Research Topics

Contemporary researchers are mainly focused on the following topics in relation to solid state physics.

Strongly Correlated Materials

These are a broad class of electronic materials which often show unusual (technologically very useful) magnetic and electronic properties, such as half-metallicity or metal–insulator transitions. The most essential feature that clearly defines clearly these exquisite materials is that the behavior of their energized electrons can never be described almost effectively in typical terms of viable noninteracting entities. The major theoretical models of the related electronic structure of these strongly correlated materials must sincerely include electronic correlation to be stringently accurate.

Quasicrystal or Quasiperiodic Crystal

These structures are typically ordered but not at all periodic. A quasi-crystalline pattern most obviously can fill all available space continuously, but it severely lacks translational symmetry. Although the crystals, according to the general classical crystallographic restriction theorem, typically possess only two-, three-, four-, or six-fold rotational symmetries, herein the Bragg’s diffraction pattern of these quasicrystals shows sharp peaks with most other symmetry orders, for instance, about five-fold.

Spin Glass

Spin glass is actually a highly disordered magnet, wherein the typical magnetic spins of the individual component atoms (the relative orientation of the magnetic poles; i.e., north and south poles in the exact three-dimensional space) are not at all aligned in any regular pattern. The term *glass* actually comes from a typical analogy between the positional disorder of a mostly conventional, chemical glass (e.g., window glass), and the highly magnetic disorder in a spin glass. In window glass or in case of any amorphous solid, the typical atomic bond structure is highly irregular; whereas in contrast to this phenomenon, a crystal has a very uniform pattern of regular atomic bonds. In all ferromagnetic solids, all magnetic spins align rightly in the same direction; this would be typically analogous to a crystal.

High-Temperature Superconductivity (HTS or High- T_c)

These are typical solid materials that behave as efficient superconductors mostly at unusually high temperatures. The first ever HTS was actually discovered in 1986 by two IBM researchers, K. Alex Müller and Georg Bednorz, who were later awarded the 1987 Nobel Prize in Physics for this discovery. Their work led to an important breakthrough in the area of discovering superconductivity in the ceramic materials.

PHYSICS, THERMODYNAMICS

Thermodynamics is the study of the relationship between temperature, heat, and bulk properties of matter such as volume, pressure, and mass. It developed in the 19th century through attempts to understand the general principles behind the newly developing technology of steam engines, and the failures of earlier theories of heat. Material bodies are treated at an aggregate level, parameterized by a few operationally well-defined properties, without reliance on detailed underlying models of how matter is composed. A few general principles, combined with the results of characteristic measurements for a given material, allow detailed conclusions to be drawn about the thermal properties and behavior of the material and its interactions with other materials.

In the late 19th and early 20th centuries, thermodynamics was supplanted, as a fundamental theory of physics, by statistical mechanics, which seeks to account for the same phenomena in terms of the behavior of large numbers of atoms and molecules. Statistical mechanics continues to use theoretical terms that originated in the theory of thermodynamics, and the relationship between the two theories is often considered the paradigmatic example of theory reduction in the sciences. After tracing the historical development of thermodynamics, this entry presents the core concepts of the study, outlines the four laws used to define thermodynamic properties and behavior, and concludes with an account of the developments in physics since the 1860s which have led to revision and refinement of the conceptual foundations on which thermodynamics was based.

Historical Development

The beginnings of thermodynamics lay in the development of an operational definition of temperature. Although primitive notions of *hotter than* and *colder than* are evident from the senses,

the development of a numerical temperature scale required materials that would consistently expand as they were heated and two fixed, reproducible temperatures that could be used to calibrate thermometers. By the middle of the 18th century, the boiling and freezing points of water had started to become adopted to calibrate thermometers based upon the expansion of mercury or of gases.

Once thermometry had advanced, comparisons could start to be made as to the extent to which temperatures changed as different kinds of actions were performed upon different materials. Joseph Black's observation that ice stayed at the same temperature, while continuing to absorb heat from other bodies during melting, led to the idea of heat or cold as a substance called *caloric*. Bodies with a lot of caloric would be hot. Bringing them into thermal contact with cooler systems would result in a flow of caloric from one to the other, until they reached the same temperature. By measuring the change in temperature brought about by this loss of caloric (calibrated by means such as the largest quantity of ice that could be melted by absorbing the caloric), the different responses of different materials to caloric could be measured.

In the first half of the 19th century, a series of experiments cast doubt upon the caloric theory of heat and led to the development of thermodynamics. In 1798, Count Rumford showed that the friction involved in boring a cannon could seemingly produce unlimited amounts of heat, a problem if heat was a conserved substance. Julius von Mayer, in 1842, and James Joule, in 1843, showed there was a fixed amount of heat that would be produced by a fixed amount of mechanical work. The quantification of the mechanical equivalent of heat suggested that heat and work were interconvertible. Instead of two distinct things, they were different instances of a single conserved property: energy.

The development of steam engines in the 18th century showed that the flow of heat could be used to extract mechanical work, such as driving a piston or lifting a weight, but even the best steam engines seemed to produce large amounts of excess heat, compared with the work extracted. This problem was first effectively studied by Sadi Carnot in 1824. Although working with the caloric theory, he discovered a limitation on the extent to which the flow of heat between bodies at

different temperatures could be used to extract mechanical work, and the limitation depended only on the difference in temperature between the hottest and coldest bodies present.

Émile Clapeyron removed the dependency on the caloric theory from Carnot's work, in 1834, but it was Rudolf Clausius, in 1851, and William Thomson, in 1852, who combined Carnot's work with the conservation of energy to produce what would become the theory of thermodynamics (Thomson coined the term in 1854). The most significant breakthrough was when Clausius showed that Carnot's analysis implied the existence of a new property, which could increase but never decrease, and which gave a measure of the limitations on which heat energy could be converted back into mechanical work. In 1865, Clausius named this quantity as *entropy*.

The theory of thermodynamics came to be expressed in two laws: the conservation of energy and the impossibility of entropy decreasing. By the 1930s, two further laws were added, clarifying the properties needed to define a temperature scale, and established how properties of materials behaved as the temperature approached its minimum possible value.

Almost as soon as the theory of thermodynamics had been developed, however, it was being replaced. From 1857 onward, Rudolf Clausius and James Clerk Maxwell started to develop an explanation of thermodynamic properties based upon atomic theories of matter; this was further developed by Ludwig Boltzmann, beginning in 1872, and Josiah Willard Gibbs up to 1903. Although these explanations faced significant conceptual challenges, their great success in accounting for the specific form of empirically measured thermodynamic properties led to its being widely accepted by the early 20th century.

Core Thermodynamic Concepts

The core concepts in thermodynamics are *mechanical work*, *thermal equilibrium*, *temperature*, *heat*, and *entropy*.

The notion of mechanical work in thermodynamics is an expression of the energy given to, or extracted from, a system by means of changes in controllable parameters, such as the height or a weight or the volume of a gas. It is derived from

Newtonian mechanics, where a force acting on a system as the system moves through a fixed distance increases the energy of the system by the product of the force and distance. The standardized measure of work is the distance that a fixed mass can be moved through a gravitational field. In a gas, the notion of force is generalized to pressure, and distance is generalized to volume. When the gas changes volume at a constant pressure, the energy of the system changes by the product of the pressure and the change in volume. If the volume decreases, the energy must increase, and work must be performed upon the gas. If the volume increases, then the energy can go down, and the pressure can be used to extract work from the expanding gas. This is how the expansion of a gas against a piston can be used to draw energy out of a system. In general, the mechanical work required is equal to the product of the change in a parameter and a generalized force acting upon that parameter.

Thermal equilibrium plays a central role in the theory. A system is in equilibrium if it is not changing over time. For thermodynamics, a more complicated notion is needed for thermal equilibrium. If a system is thermally isolated, so no heat can be exchanged with other systems, and all the controllable parameters are fixed at some value, then according to thermodynamics the system will approach coming to rest in a unique equilibrium state. This state can be characterized as a function of the controllable parameters, the temperature and the energy of the system. This function, the *equation of state*, is the starting point of most thermodynamic analyses. For each material, it must be empirically determined which are the relevant controllable bulk parameters and what form is taken by the equation of state. When two systems are brought into thermal contact with each other, they will exchange heat until they reach a joint state of thermal equilibrium with each other.

The notion of temperature needed careful clarification for its use in thermodynamics. A thermometer is, at its simplest, a system which has an observable property that increases steadily and consistently as the system is heated. A thermometer has no other controllable parameters, so its equation of state depends only on the property and energy. If a thermometer is brought into thermal

contact with another system, heat will be exchanged until they have reached thermal equilibrium. The observable property of the thermometer then indicates the temperature of the system. To be a good thermometer, the temperature of the thermometer would need to be very sensitive to the changes in its internal energy, so that only a small quantity of energy needs to be exchanged with the measured system, introducing negligible changes.

However, this might still allow a system to show different temperatures depending upon the type of thermometer used. The key idea for thermodynamic temperature is that there is a universal temperature scale, so an ideal thermometer is measuring an actual property of the world. For this, thermodynamics requires that whenever two systems are individually in thermal equilibrium with a third system, they must also be in thermal equilibrium with each other. If the third system is the thermometer, this ensures that it records the same temperature for all systems in thermal equilibrium with each other. If two of the systems are thermometers, the requirement ensures that the different thermometers measure the same property, even if they are constructed from different materials and physical properties. Different thermometers might define different scales, but a conversion scheme in principle exists between the different scales. The Fahrenheit and Celsius scales are two examples. The Kelvin scale was based on the equation of state of an ideal gas, which led to the understanding that there was a minimum point on all temperature scales: the absolute zero of the Kelvin scale.

When two systems are brought into thermal contact, energy can be exchanged between them without any work being performed. In thermodynamics, this kind of energy exchange is called *heating*. Prior to thermodynamics, heat was considered a kind of substance, like a fluid, and this language persists (e.g., heat *flows*). Now, however, only the total internal energy of a system is considered to be a property of a system in thermodynamics. The energy is not divided into separate quantities of heat and work; instead heat and work quantify two ways in which the internal energy of a system may be changed.

Probably the most important and unexpected concept in thermodynamics was the existence of

entropy. When an object's energy changes by a small amount, whether through work or heat, the change in its entropy is given by the ratio of the change in its energy to its temperature (measured in the Kelvin temperature scale). In any exchange of energy between systems, the second law of thermodynamics states that the sum of the entropies of all systems involved cannot go down: It must either stay constant or increase.

When two objects at different temperatures are brought into direct thermal contact, such as an ice cube placed in a glass of water, they exchange heat until they come to the same temperature. Conservation of energy requires that the heat emitted by one is equal to the heat absorbed by the other. The object losing heat decreases in entropy, while the object absorbing heat increases in entropy. As the change in entropy is given by the same quantity of heat but divided by their different temperatures, the hotter water has a smaller change in entropy than the colder ice. For the total entropy to increase, the ice needs to increase entropy and the water needs to decrease entropy, so heat must be emitted by the water and absorbed by the ice. Ice in water melts, cooling down the water. This holds in general: When two objects at different temperatures are brought into thermal contact, heat must be emitted by the hotter object and absorbed by the colder. Entropy not only unites the disparate phenomena of heat spontaneously flowing only from hotter to colder objects but provides an explanation of why no examples of the reverse processes can be found.

The notion of entropy explains much more than this. It was developed from the study of heat engines. A steam engine allows heat to flow from a heated body (steam) into a lower temperature system (the heat sink, typically the environment) but extracts some of the energy emitted by the hotter body and converts it to mechanical work. In the case of a steam engine, this is typically by driving a turbine, which might pull a pulley, drive a pump, or generate electricity. Carnot also contemplated a heat pump, the reverse of a heat engine, in which heat is extracted from a cold system (making it colder) and transferred to a hotter system. Such a process would require work to be performed, adding to the heat in the system. Modern examples of heat pumps are refrigerators and air conditioners. If a heat pump and a heat

engine work together, Carnot showed there is a maximum efficiency at which they can operate. In the case of the heat engine, there is a maximum amount of heat which can be extracted from the hot body and converted to work. For the heat pump, there is a minimum amount of work required to cool down the colder system.

In an entropic analysis of the heat engine, the extraction of some of the heat, in the form of mechanical work, reduces the amount of heat that is being absorbed by the colder object. This must reduce the extent of its entropy increase. The maximum amount of work that can be extracted is just enough so that the increase in entropy of the colder body is no more than the entropy reduction of the hotter body. Extracting any more than this would lead to a net decrease in entropy, so real heat engines cannot extract more than this amount of work.

For a heat pump, if heat could be transferred from a colder body to a hotter body without assistance, then the reduction in entropy of the colder body would be greater than the increase in entropy of the hotter body. This would require the total entropy to decrease. If, however, some work is performed upon the system, adding extra heat to the hotter object, then the entropy increase in the hotter object becomes larger. The minimum amount of work needed is just enough so that the entropy increase of the hot body just matches the entropy reduction of the colder body, and the net change in entropy is zero. Real refrigerators require at least this amount of work to operate, and they dissipate this work as extra heat. Entropy thus characterizes which processes are possible and which are not and also gives quantitative values on the amount of work required to effect changes in systems.

The concept of entropy, and the law of its increase, unified a large number of phenomena, explaining why some are widely observed and their reverse processes are almost never observed.

The Laws of Thermodynamics

Thermodynamics is conventionally stated in terms of four laws (the exact phrasing of which varies from source to source) that are used to define thermodynamic properties and behavior. For

historical reasons, the laws are numbered from zero to three (the zeroth law, while logically prior to the first, second, and third laws, was only given a precise formulation by Ralph Fowler and Ernest Guggenheim in 1939). The first and second of these laws are often expressed as forbidding types of perpetual motion.

The zeroth law is intended to assert the existence of a universal temperature scale. A typical formulation is: "If two systems are each in thermal equilibrium with a third system, they are always in thermal equilibrium with each other." This ensures that different thermometers showing systems in thermal equilibrium with each other are at the same temperature as each other. Temperature is therefore defined as a quantity that parameterizes thermal equilibrium.

The first law is often expressed as the existence of a conserved quantity called *energy*. A typical formulation is "The change of energy of a system is equal to the sum of the heat absorbed by the system and the work done upon the system." Because heat and work characterize exchanges of energy between systems, the gain in energy by one system must equal the loss in energy by all other systems.

The first law is often stated as the impossibility of a *perpetual motion machine of the first kind*. A perpetual motion machine is one that is able to complete a sequence of operations in a fixed amount of time that return it to its original state, and it is therefore able to perform the cycle of operations again any number of times. A machine of the first kind is one that can perform such a cycle, in thermal isolation, and perform work upon another system while doing so. It would violate the first law of thermodynamics, because its internal energy must remain unchanged and the heat absorbed must be zero, but the work extracted from the system is not zero. This would mean energy was not conserved over the course of the cycle.

The second law expresses the existence of a property called *entropy*, which can increase but cannot decrease. A typical formulation is "Heat cannot spontaneously flow from a colder system to a hotter system." As the entropy change in a system is given by the heat flow divided by the temperature, a flow of heat against the temperature gradient would result in a small entropy increase in the hotter system and a large entropy

decrease in the colder system, giving a total decrease in entropy. Entropy decreases are possible in individual systems, but only in processes where at least as much entropy increase occurs in other systems.

The second law is often stated as the impossibility of a perpetual motion machine of *the second kind*. A machine of the second kind is one which can perform a cycle of operations, returning to its original state, while extracting work from a single system, cooling it down in the process. Such a machine does not violate the first law of thermodynamics, as the work extracted equals the reduction in energy of the cooling system. However, the entropy of the cooling system would be decreasing, and there would be no compensating entropy increase anywhere else.

The third law of thermodynamics concerns the inability to reach the absolute zero of the temperature scale. A typical formulation is "The entropy of a system approaches its minimum value as the temperature approaches zero." At absolute zero on the temperature scale, the entropy of the system becomes independent of the values of the controllable parameters in the equation of state. Cooling a system down involves varying these parameters in cycles to extract energy from the system. As the entropy approaches its minimum, the entropy change from varying the parameters becomes even smaller, in such a way that no finite number of cycles can reduce the entropy all the way to its minimum. As a result, it is impossible to reach absolute zero temperature in a finite number of cycles.

Further Developments

From the 1860s, the kinetic theory of gases identified heat as the motion of atoms and molecules. *Pressure* is the force exerted by a large number of particles colliding with the side of a container holding them, and the temperature of a gas is an expression of the total kinetic energy of its motion. In 1872, Ludwig Boltzmann identified a function of the microscopic particles which could fulfill the role of entropy. Although highly successful, this raised significant conceptual problems for thermodynamics, with particular problems for the second law.

In 1867, Maxwell imagined a tiny shutter between two boxes containing a gas, initially at the same temperature and pressure on both sides

of the shutter. If the shutter can be opened only when a molecule approaches from the left, and closed when a molecule approaches from the right, then gradually the gas will accumulate in the box on the right. This will lead to a pressure difference between the two boxes, and the gas can be allowed to flow back into the box on the left, driving a turbine to extract work on the way. This would be a perpetual motion machine of the second kind.

In 1876, Johann Joseph Loschmidt raised the problem that the laws of physics are symmetric in time. If a system can approach thermal equilibrium, then it must be possible that a system can depart from thermal equilibrium, undermining the whole concept. Equally problematically, if processes that increase entropy are possible, then processes that decrease entropy should also be possible.

In 1890, Henri Poincaré showed that a closed system governed by Newton's laws, if left isolated for long enough, must return arbitrarily close to its initial state. So if an ice cube were dropped in a glass of water, and the system was completely isolated, the ice cube would melt but at some point in the future it would have to spontaneously reform.

The resolution of these problems is now generally considered to be that reductions in entropy are possible, but under normal circumstances are so unlikely that they are never observed. The source of this implausibility is that the initial state of the universe was in an extremely low entropy state, and this biases the processes that occur against observing reductions of entropy on any reasonable timescale.

PHYSICS, 20TH CENTURY

In the 20th century, physics expanded at a rapid pace, on the one hand continuing to further clarify and articulate the theories it inherited from 19th-century physics, and on the other coming to grips with the various revolutionary developments arising at the turn of the 20th century. These developments were prompted by a number of observations that seemed simply incompatible with our basic understanding of the laws of nature—for example, black body radiation, radioactivity, and the mismatch between electromagnetism and mechanics. The 20th century saw important developments in the theoretical tools at the disposal of physicists in their efforts to interpret, understand, predict, and control the physical world.

This entry highlights several important conceptual developments in physics in the 20th century, including quantum theory, particle physics, the special theory of relativity, the general theory of relativity (along with the big bang theory). The entry also mentions briefly some other developments in theory flowing from 20th century physics, and their connections to other physical disciplines. Because of space limitations, we must leave details of these other important developments and technical issues to other entries in this encyclopedia.

Background

Constituents of Matter

Although in the west the Greeks first hypothesized the concept of the atom around two-and-half millennia ago, for long afterward there was no true theoretical development of the concept. During the 19th century C.E., the facts concerning the existence of atoms had been indirectly confirmed, and a more detailed theoretical picture was being developed in order to make use of the concept. The picture of the atom at that time was much different from what it is now. In the 19th century, the structure of atom was thought to be that of a spherical globule with more-or-less uniform density. Nowadays, the actual structure is thought to consist of a very small and heavy nucleus, around which swarm very lightweight,

negatively charged particles called *electrons*. The name *atom*, meaning “indivisible” in Greek, has thus been shown to be a misconception. The atom is not the basic building block or the smallest part of a molecule; rather, it is constructed of smaller units. Furthermore, the nucleus is composed of neutrons and protons, each of which actually weighs almost 2000 times more than an electron. As their names suggest, the neutron is neutral, with no amount of electric charge, whereas the proton is positively charged. It was 1897 when the existence of the electron was confirmed; previously, it had been thought that the electron was a form of liquid matter rather than a microscopic particle. In the first half of the 20th century it was commonly supposed by scientists that the basic components of matter were neutrons, protons, and electrons. Since then, high-energy accelerators have disclosed the fact that neutrons and protons are made up of three quarks. *Quarks* are point-like, microscopic units with electric charges that are only one-third and two-thirds of the total charge of the electron. In short, matter could be divided by the scientists into smaller units to an ever-increasing extent. After centuries of experiments and discoveries, a splendid vivid picture of the basic constituents of matter has been achieved. It remains to be seen when this “reductionism” of matter will cease.

Developments in Radioactivity

Owing to the evolutionary phase of physics during the course of the 19th century, highly complex problems could be handled by classical mechanics: detailed analysis of macroscopic situations; kinetic theory and thermodynamics were developed significantly; physical and geometrical optics in terms of electromagnetic waves could be well understood; there was widespread acceptance for the laws of conservation of momentum (and mass) and energy. The impact of these and other developments produced a general idea that all physics-related crucial laws had been discovered. The only aim of the discipline from then on would be to pinpoint and solve the minor issues of physics and develop better means of measurements and methods. But the notion of the completeness of the classical theories suffered a serious setback, and around 1900 critical doubts

arose about them. For example, inadequacies had begun to appear in James Clerk Maxwell’s theory regarding the photoelectric effect, black body radiation, and energy distribution. Paradoxes were noticed with some of the theories when pushed to their limits of application. Some prominent physicists, such as Wilhelm Wien, Emil Cohn, and Hendrik Lorentz, believed that all physical laws could be based on Maxwell’s equations when modified appropriately. However, it was soon realized that new ideas were required in order to resolve the problems of classical physics. Indeed, the world of physics was shaken by a major revolution at the beginning of the 20th century that marked the emergence of modern physics. For his crucial discoveries of electrons and isotopes, and the construction of the first mass spectrometer, the British physicist J. J. Thomson was awarded the Nobel Prize for Physics in 1906. Unexpected forms of radiation were detected by researchers in the 19th century. In 1895, the sensational discovery of X-rays took place through the work of William Röntgen. The emission of radiation by certain elements was discovered by Henri Becquerel in 1896. With the discovery by Marie and Pierre Curie of the new radioactive elements radium and polonium, questions began to be asked about the nature of matter and indestructibility of the atom. Two of Becquerel’s radiation forms were derived from the element helium, and electrons through the efforts of Frederick Soddy and Ernst Rutherford. Two types of radioactivity were identified by Ernst Rutherford; in 1911, he proposed that the atom consisted of negatively charged electrons surrounding a positively charged nucleus at the center. However, the stability of this structure was not in accordance with classical theory. In the late 19th century, two other theories arose that could not be explained by classical theory. One of these had to do with Albert A. Michelson and Edward W. Morley’s experiment that disconfirmed the existence of the so-called *luminiferous aether*, hitherto a preferred frame of reference for explaining electromagnetic phenomena. Throughout the 1930s, a preeminent focus of physical and chemical sciences was that of research on radioactive decay and radiation. It is during this time that the doors to the domain of atomic energy were opened through the discovery of nuclear fission.

Quantum Mechanics

Quantum mechanics is one of three important 20th-century revolutions in physics. It basically governs the dynamics of the microscopic and subatomic objects such as the atoms and electrons. Its development was meant to solve the conceptual puzzles of the theory of radiation and the constituents of matter, mentioned above; it also made possible further developments in the theory of matter, leading to our current standard model of particle physics, the story of the basic constituents of matter. One of the major features of the quantum mechanics is the principle of uncertainty, as first proposed by Werner Heisenberg, which argues, in part, that the exact position of any rapidly moving charged object like an electron in an atom can never be located with certainty—instead, the electron's position can be determined probabilistically. Hence, the thought arose that a typical electron in an isolated atom is like a cloud with very dense regions of the cloud representing probable places where the chance of finding an electron is most likely, and much less dense regions where this electron is least likely to be found. Another significant feature of the field of quantum mechanics is *discreteness*. For example, a specific electron in an isolated atom can assume only a few particular types of motions, called *states*, and particular values for its energy to stay in those states or levels which are likely, called *energy levels*. The glaring discrepancy in explaining black body radiation in the UV range of the spectrum also, known as the *ultraviolet catastrophe*, was rightly and clearly solved by the new specialized theory of quantum mechanics. Thus, it was during the first 30 years of the 20th century that the basic conception and evolution of quantum mechanics took place. In 1900, Max Planck introduced the basic ideas of quantum mechanics. He was thereafter awarded the Nobel Prize in physics in the year 1918 for discovering the quantified nature of energies, or *quanta*. The quantum theory was more prominently accepted after the Compton effect clearly showed that light indeed carries momentum and can thus scatter particles. During this time Louis de Broglie established his theory of wave-particle duality, which furthermore paved the way for the acceptance of the critical theories of quantum mechanics. In 1905, Albert Einstein successfully established his

theory on the photoelectric effect by using quantum mechanics and again in the year 1913, Niels Bohr effectively explained the stability of Rutherford's model by using quantum theories. Thus, the general quantized theory of the atom gave a new dimension for the beginning of an era of full-scale quantum mechanics around the year 1920. Heisenberg, Max Born, Paul Dirac, Wolfgang Pauli, and Erwin Schrödinger were some of the eminent physicists who extensively participated in the development of quantum mechanics during the 20th century. Heisenberg's uncertainty principle, proposed in 1925, asserts the impossibility of simultaneously and precisely measuring the momentum *and* the position of a moving charged particle; that is, it's possible to measure one or the other, but not both. Niels Bohr's ("Copenhagen") interpretation of quantum mechanics denied the possibility of any type of fundamental causality in quantum mechanics. In its new form, quantum mechanics became an almost indispensable tool in the explanation and investigation of the different phenomena at the atomic level. In 1920, Sir Satyendra Nath Bose's work on the *photon*—a particle representing a quantum of light—and its significant role in quantum mechanics led to the foundation of Bose-Einstein statistics, the theory that describes the fundamentals of the Bose-Einstein condensate. After this interesting discovery in quantum mechanics, the *spin-statistics theorem* emerged, which gave rise to the possibility of a particle of either being a *boson* (i.e., it follows Bose-Einstein statistics) or it can be a *fermion*, which follows the Fermi-Dirac statistics. Later on, it was found that all the fundamental bosons can actually transmit forces, like the photons, which are capable of transmitting light.

Subatomic Forces and Particle Physics

In the early 18th century, three fundamental forces were known to science: gravity, the electric force, and magnetism. By the very end of the 19th century, however, views had changed, and now it was understood that there were actually only two types of fundamental forces: the electric and magnetic forces are thoroughly unified into one fundamental force, which is called the *electromagnetic force*; this can be counted as one of the greatest achievements of 19th-century physicists. It turns

out that all magnetic fields are created by the rapid motion of charged particles, and these charges are perhaps the basic source of the electric force. Hence, in 1899, many scientists thought that there exist only two major fundamental forces: the electromagnetic force and gravity. And since these physicists had a fairly thorough understanding of both of these forces; they thought that they knew all of it. But the story took a new turn, specifically during the mid-20th century, when two new types of fundamental interactions were discovered. They were found to be subatomic—meaning that they act at scales much smaller than an average atom—and to reside inside the nucleus. The strong nuclear force binds the neutron and the proton to form the nucleus. This force also holds together the respective protons and neutrons in a nucleus. Similarly, a weak sub-nuclear force is responsible for the certain radioactive decay of nuclei as observed in case of many elements. In 1969, the three pioneer physicists Sheldon Glashow, Abdus Salam, and Steven Weinberg succeeded in a process of unifying this weak forces with electromagnetism. Thus, the basic fundamental forces are the strong nuclear force, electromagnetic interactions, and the force of gravity.

Special Relativity

Newton's laws of classical mechanics largely fail to explain phenomena at short distances and at high speeds, which can be correctly explained by quantum mechanics. At the very beginning of the 20th century, Albert Einstein developed the special theory of relativity, which greatly explains the dynamics of objects traveling at extremely high speeds. The effects of the laws of special relativity are only applicable for things moving at a velocity approaching the speed of light. One typical effect that has come to be widely known is the mass–energy equivalence, as embodied by the famous mathematical equation $E = mc^2$, meaning that energy equals mass times the speed of light squared. An enormous amount of energy can therefore be produced by the destruction of a small amount of mass. This not only explains the vast amount of energy stored in stars but also served as the basis of atomic bombs. One of the very interesting consequences of this special theory of relativity is the unification of space and

time into a typical four-dimensional world. Of the three papers published by Einstein in 1905, the third, titled “On the Electrodynamics of Moving Bodies,” clearly and strongly laid out his theory of relativity, which would change the course of physics. The theory was actually derived from Einstein's perspective on the luminiferous aether. Einstein realized that if the aether actually, exists it is more of a medium in which electromagnetic waves travel. The aether also provides a fixed background or a perfect reference frame against which all the motion that exists in the universe can be effectively measured. Any arbitrary point in the universe can be taken to be as the origin where three perpendicular axes, designated as x , y , z , meet. Thus, any particular point in the universe can be defined by three numbers, thereby specifying its actual distance from the origin along with the three axes. To clearly describe the path of a moving particle, one would only need to know the exact values of all three numbers at different intervals of time. The aether was considered to be the absolute frame of reference, as it was thought to be stationary, while any object or wave would move with respect to this stationary frame of reference. Scientists on Earth can only measure the absolute relative motion of any object with respect to the instruments stationed on earth in an absolute reference frame. Thus, to determine the absolute motion of that particular moving object, these scientists would need to accurately measure the absolute motion of each of these instruments with respect to the aether. Initially, scientists believed that the earth was actually the unmoving center of everything, but they realized that earth was actually part of a larger solar system, and they placed the Sun as the unmoving center of the universe. With newer perspectives, the view of space and time changed and so did the mathematical interpretations governing Maxwell's equations and Newton's laws of motion. In a postscript to his 1905 paper, Einstein raised the question of whether the inertia of a body depends on its energy content—which can be considered the most dramatic surprise of the theory of relativity at that time. Electromagnetic energy must clearly travel at the constant speed of light, but anything which has mass can never achieve that much speed irrespective of the magnitude of force acting on it for whatever duration. Thus, the higher an object's

velocity is in the observer's reference frame, the more magnitude of force must be exclusively applied to increase its speed by the requisite amount. The work done on it in this case actually causes the mass or inertia of the object to increase considerably.

General Relativity

During the later years of the 19th century, physicists believed that the universe is actually made up of only thousands of stars, which are not arranged in any particular pattern. The most distant stars were actually thought to be about 100,000 light years away from the earth. However, during the 20th century, with the development of larger and much better telescopes, astronomers were able to observe objects that were about 10 billion light years away. Furthermore, they have found that the universe actually contains a large number of interesting structures. It is not until the year 1920 that scientists recognized the existence of galaxies, which are large collection of distinct stars grouped together in a relatively localized area of the universe of about 100,000 light years in size, usually containing one hundred billion stars. Some of these galaxies are pancake shaped, while others are spiral shaped and are referred to as spiral galaxies. Some galaxies are ellipsoidal, and many others are irregular. The galaxy in which the Earth and the Sun reside is called the Milky Way, named after the band of whitish hue that can be observed from Earth on a clear night. The next two large galaxies nearest to the Earth are the large and small Magellanic clouds, which are irregularly shaped and can be only observed from the Southern Hemisphere of the Earth. Andromeda is the third nearest galaxy from Earth; it is spiral shaped. During the last three decades astronomers have made a significant finding that, occasionally, 100 to 1,000 galaxies group together to form galaxy clusters. They also found that there are regions in the universe which are devoid of any galaxies; these regions are called *giant voids*. In trying to understand how to make his special theory of relativity fit with gravitation theory, Einstein developed the general theory of relativity, a theory that explained much of what we see in the large-scale structure of space, including the astronomer Edwin Hubble's observation

of the difference in the wavelengths of similar stars at different distances from the Earth and his postulation that the most distant stars are moving away from the Earth at greater speeds.

Einstein's second revolution in 20th-century physics is general relativity, his theory of gravitation. The general relativity theory provides deeper insights into the actual nature of gravity. Developing the general theory of relativity took Einstein to unusual mathematical territory. A simple experiment might provide a clear perspective of this theory and its analysis. Let us suppose that in a laboratory an observer is involved in measuring the motion of some falling bodies. There is no air resistance, because the bodies are in separate vacuum chambers within the laboratory, and the bodies are magnetically and electrically neutral. The observer's only goal is to measure the force of gravity on these bodies, which are free from all other forces. The observer learns that the velocity of these bodies gradually changes in a typical way, and it is the same for all such bodies regardless of any difference in their masses. The vertical motion of these bodies continuously increased in the downward direction at a rate of 9.8 meters per second, while their velocity parallel to the ground remained constant. The observations made during these experiments produced a very clear conclusion. The laboratory, along with the observer is, actually in a gravitational field with an acceleration of 9.8 meters per second, or 32 feet per second, simply called *g*. However, if an observer is considered to be on the falling body, the whole perspective would change. To an outside observer, the laboratory and the lab observer were viewed as accelerating upwards with a force of one *g*. Thus, the main fact is if neither of the observers was allowed to see outside into the surroundings, they would never be able to conclusively predict whether they are in any accelerated frame of reference or in a gravitational field. Pursuing this thought further, Einstein was able to unify space and time together into a four-dimensional space-time grid. People usually envisioned position as defined by a three-dimensional geometry or space, as a grid of imaginary meter sticks which basically stretch themselves to infinity in three different directions perpendicular to each other in space. But Einstein argued the presence of a fourth dimension: *time*,

denoted by the t axis through which everything gradually moves at a specific rate of one meter per second. Now, to distinctively envision Einstein's concept of space-time, a four dimensional grid with markings x , y , z , and t can be imagined. Photons have no specific mass or else they would have to travel much slower than the speed of light according to the concepts of the special theory of relativity. When Einstein published his general theory of relativity in the year 1915 many physicists were seriously determined to test his predictions. Fortunately, the solar system, on rare occasions such as a solar eclipse, provided a way to prove these predictions true. When starlight on the way to Earth passes close to the Sun, solar gravity actually diverts the path of the light by a measurable amount. However, during a total solar eclipse, astronomers are capable of viewing and measuring the distinct pattern of stars that are normally invisible in a bright sky. The eclipses rarely occur—only once or twice a year—but they usually occur along very narrow paths as the shadow of the Moon sweeps across the surface of the Earth. In 1917, when Einstein was delicately exploring the implications of his newly described mathematical theory of relativity, he discovered that his theory had predicted the existence of a continuously contracting or expanding universe. At this time he also noticed that the exquisite solution to his mathematical equations actually included a typical and apparently arbitrary value termed *the cosmological constant*, which can ascertain different values leading to different rates of contraction or expansion. Only one particular value can lead to stability, and that was the value on which nature had settled. Although Einstein considered the presence of the cosmological constant as his greatest mistake, the term eventually made a comeback at the very end of the 20th century and is still deeply intriguing physicists. Now physics has created more problems than it has actually solved, starting from Einstein's theories of relativity to Neils Bohr's structure of atoms; new areas have to be opened, leading to a full-scale effort to virtually reestablish physics on totally new fundamental principles. Einstein's general theory of relativity, proposed in the year 1910, concluded that space is actually highly curved and finite in size. Einstein, by expanding relativity to the accelerating

reference frame, posited an equivalence between the force of gravity and the inertial force of acceleration.

The History of the Universe

Toward the end of the 19th century, scientists thought the age of our universe was about several hundred million years. Moreover, very little was known about the history of the universe. Today it is understood that universe began as an almost inconceivably hot concentration of energy and mass. As time advanced, the concentrated universe expanded immensely, which means that the basic fabric of space was highly stretched, and through this stretching, the material was rapidly dispersed and the universe eventually cooled. Finally, gravity affected very high concentrations of matter, enabling them to collapse rapidly into individual galaxy clusters at very large scales and others into stars at much smaller scales. This process of star formation with the aid of gravitational collapse also continues today, typically at a much slower rate. The application of terrestrial physics to the rest of the universe, to be able to infer its time evolution and to understand the mechanisms of that evolution marks a significant moment in the development, expansion, and application of theory.

Other Significant Advances in Theory

In addition to the revolutions of its early part, the 20th century was marked by significant advances in the nature of the theories it employed.

The theories in this domain of *nonlinear and chaotic systems theory* are important for their practical results in understanding, for example, weather, climate, fluid flow, and scaling phenomena. They are also important because they mark a significant change in our understanding of the relation between determinism and prediction, which while conceptually distinct had always been connected in most discussions of physical phenomena. Chaotic systems are among the non-linear types. They have a peculiar feature that while their equations of motion, and the solution spaces of those equations, are completely deterministic, they are highly resistant to prediction and indeed it can be shown that in many regimes their exact

behaviors are *in principle* impossible to predict. The slogan here is that no matter how small a change one makes in initial conditions, there can be arbitrarily large differences in final outcomes. The significance of this is that, since our observations are, in principle, of finite precision, then no matter how precisely we can determine the initial conditions, the outcomes will be unknowable. This kind of unpredictability is totally different from that introduced by quantum theory, where the suggestion in most quarters is that systems it studies are indeterministic. But chaotic systems—fluid flows for example—can be totally determined and yet unpredictable even so. (For more on this, see the entry on Complex Systems.)

A second major theoretical development is in the connection between thermodynamics and the microstructure of matter studied in kinetic theory. This connection and theoretical advances that resulted from studying it had important results in thermodynamics itself as well as profound effects on theory in solid-state physics, on gravitational theory, as well as on perturbation theory.

The Twentieth Century saw important advances in physics that shaped and continue to shape our understanding of the world, as well as our understanding of physical theory and its application to the world.

PLATE TECTONICS

Plate tectonics is not only the central theory of earth science but also an extraordinary case for those wishing to understand the social acceptance of a theory, as its main postulates circulated for a long time but did not generate consensus. Plate tectonics theory considers that the Earth is composed of layers, and the rigid outer layer, known as the *lithosphere*, is broken up into several plates that are in movement. The theory emerged in the 1960s anchored in two principles: seafloor spreading and continental drift. It explains how mountain ranges, earthquakes, volcanoes, and continents fracture, how oceans form shorelines, and other features. The impact of the theory of plate tectonics to geoscience has been compared to that of Darwin's theory of evolution on biological sciences. It is said to have deployed a new paradigm that profoundly changed the dominant ideas about how the Earth works.

The geophysicist Alfred Wegener is usually recognized as the precursor of the theory, for his development of the continental drift theory in 1912. But it took 50 years until his ideas about the movement of the continents were vindicated. As will be described and discussed in what follows, plate tectonics theory is not only a major geoscience theory, but its history is also a controversial case in which rationalist and constructivist approaches argue about why it was so difficult for scientists to accept that the landmasses were actually moving.

The Emergence of Plate Tectonics Theory

The understanding of the structure of the seafloor was one of the pillars of the theory development and, perhaps unexpectedly, war became an ally for its purpose. German submarines caused heavy losses to the allied forces in World War II, which prompted the U.S. Navy to improve knowledge in geophysics and oceanography to provide means to detect enemy submarines. Many important scientific discoveries took place within this context. The U.S. Navy asked Maurice Ewing, then working at the Woods Hole Oceanographic Institution, to investigate why sonar equipment tended not to work well in the afternoon. This led Ewing to realize that temperature effects were bending the sound waves in such a way as to create a *shadow zone*, where sonar transmissions went undetected. This knowledge was then used by the Navy to better detect enemy submarines. Harry Hammond Hess, an American geologist who would have a major role in the development of plate tectonics theory, was also involved in war affairs. He was captain of a ship in charge of echo-sounding of the Pacific basin. Hess discovered that bottom of the Pacific floor was not smooth as expected, but full of hundreds of flat-topped mountains. Intriguingly, these mountains looked like their tops had been eroded by wind, but they were actually a few kilometers under water. Hess proposed an audacious hypothesis: Those mountains under the ocean were drowned ancient islands.

The following years saw a reinforced encouragement to geophysics, particularly within the context of the cold war. The leaders of the United States, of the Soviet Union, and of the United Kingdom reached an agreement to ban further testing of nuclear weapons. The problem was the undeveloped capacity to test underground violations through seismology. The solution came into the shape of a new organization that would improve earth science: the World-Wide Standardized Seismographic Network. Funded by the U.S. government, this global network deployed approximately 120 seismographic stations that generated an unprecedented amount of seismic data. At the same time, the Soviet Union deployed a similar system through the Unified System of Seismic Stations, with its own 168 seismic stations.

Other scientists, such as Edward Bullard and Patrick M. S. Blackett, also got involved in war affairs, mainly with geomagnetism research. All of them were aware of the continental drift theory and had it in mind while analyzing their data. By the mid-1950s, Blackett and his group in London argued that the variations in the earth's magnetic field showed that rocks had not remained stationary relative to Earth's magnetic field: This variation would support the theory of continental drift. Earth's ancient magnetic field can be traced in rocks because minerals indicate, like any magnet suspended in Earth's field, the direction to the magnetic pole at the time the minerals were crystallized or deposited. Studies in the 1950s showed that each continent yielded different results, but these differences could be reconciled into the same path by envisioning the joining the continents as suggested by Wegener. In other words, this paleomagnetic analysis implied that the poles' geographic variations could be explained by the wandering of the continents. A few years later, Hess supported Blackett's point of view by adding an explanation: Mantle convection currents might drive continental drift.

For centuries, it has been known that there are different kind of rocks in the Earth's interior. The Earth is made up of three main components, or layers, which vary by composition and behavior: the crust, the mantle, and the core. A relatively thin crust sits on top of the mantle. The mantle is much thicker than the crust; it contains 83% of Earth's volume and has a depth of 2,900 km (1,800 miles). Finally, beneath the mantle is the core, which extends to the center of Earth, some 6,370 km (nearly 4,000 miles) below the surface. There are two types of crust, *continental* and *oceanic*. The outer shell of our planet (crust and upper mantle) consists of the coolest part of the Earth, called the *lithosphere*. According to plate tectonics theory, here is where the plates are: The lithosphere is broken into several separate, rigid blocks, or plates. Below is the *asthenosphere*, a much hotter and more fluid layer. Here is where convection currents are generated; because of its ductility, the asthenosphere is able to deform or stretch. Tectonic plates rely on this viscous layer, which allows them to move. Convection currents generated in the asthenosphere push magma—molten or semi-molten rock—upward through volcanic vents and

spreading centers to create new crust. And by putting stress on the lithosphere above, they may also provoke earthquakes. According to Hess, mantle convection currents are the force that moves the plates. Where the edges of the plates meet, earthquakes take place. But several other things may happen as well. If those plates carry continents, which are lighter than the ocean floor, they may collide, causing high mountains to rise.

Hess postulated that molten rock from Earth's mantle emerges from active volcanoes in the ocean. As the magma cools, it spreads, creating a successively younger ocean floor and pushes apart the continents, as new ocean crust spreads away from the ridges. Hence, the ocean floor is younger than the continents. This process is called *seafloor spreading*, and it creates new crust. Samples collected from the ocean floor indicate that the age of oceanic crust increases proportionally with distance from the spreading center. These age data also allow researchers to determine the rate of seafloor spreading, which varies from about 0.1 cm (0.04 inches) per year to 17 cm (6.7 inches) per year. So new ocean floor is continuously being created. But tectonic plates may also crash into each other at *subduction zones*, where the edge of the denser plate slides beneath the less dense one, melting back into the Earth's mantle. Subduction destroys old crust. In a sort of balance between spreading and subduction, the shape and diameter of the Earth remains constant. All these processes with the oceanic crust are accompanied by much volcanic activity and by earthquakes as the crust repeatedly rifts, heals, and rifts again.

Hess's report, "The History of Ocean Basins," was formally published in 1962. Overall, Hess supported Wegener's theory of continental drift, as Hess reasserted that the once-joined continents had separated into the seven that exist today, and they had done so because they are transported by the shifting tectonic plates on which they rest.

The Continental Drift Controversy

Through plate tectonics theory we think about the Earth as a dynamic structure, with continents moving away from each other. For centuries the Earth was conceived as a rather stable structure, with no internal movements at all, or at most with

vertical motions (volcanoes and sinkings), but sideways movements of Earth's layers was not an option. Plate tectonics has transformed the way we view the surface of the Earth. But this revolutionary conception of the Earth was already present or implied at the time of continental drift theory. Proponents of plate tectonics, including Hess, recognized Alfred Wegener's continental drift theory as the forerunner of their work.

Born in Berlin in 1880, Wegener obtained a doctorate in astronomy in 1905. He then pursued a strong interest in the field of meteorology and polar research. In 1906, Wegener participated in the first of his four Greenland expeditions, where he took meteorological measurements in the Arctic climatic zone. He then obtained a position at the University of Marburg, lecturing in meteorology and astronomy. He first became aware of the problem of the continents' structure and was inspired to propose the initial sketches of what would later become his continental drift theory as a result the impact of his having noticed the complementarity of the Atlantic coastlines on a map in 1910. From that moment, he carried out a series of readings that influenced his ideas even more. Previously, in his book *The Face of Earth* (1883), Eduard Suess, an Austrian geologist, had brought to his colleagues' attention the very large dislocations of the Earth's crust. Suess even coined the word *Gondwanaland* for a proposed paleo-supercontinent consisting of Africa, South America, India, and Australia. Finally, in 1912 Alfred Wegener published his theory of continental drift, 50 years before Harry Hess was to reaffirm it with the plate tectonics theory.

Wegener argued that several millions of years ago, all continents were united in one supercontinent that he called *Pangea*. Later on and slowly, during the Cretaceous period, Pangea began to break apart. At that period, what we now recognize as the American continent began to drift away from Europe and Africa, while Asia separated from the Antarctica and South Africa by rotating counterclockwise. The movement didn't stop, as continents continued to drift away from one another, causing, for instance, the separation of Australia from Antarctica. In 1915 Wegener published his theory in a more developed way, in his book *The Origin of Continents and Oceans*. The title itself was quite explicit about the

explanatory power of the horizontal displacement of the continental masses.

Continental drift theory wasn't just a bold speculation. Wegener provided a diversity of evidence supporting his theory. He argued that the continents' margins matched, suggesting that they had once been united and then split apart. He also analyzed the distribution of similar fossils and current flora and fauna, which suggested extensive interchange of fossil species between continents during certain geological periods (in other words, what is today a genus or family was once a species in prehistoric times, therefore there must have been exchanges that could only have taken place if the lands had been connected). The several geological structural similarities among the continents as well as the coastline location of mountain ranges were additional elements that supported his theory. His own background and experience also proved useful to bolster his theory, as the longitudinal measurements from the Danish Greenland expeditions indicated a present-day westward displacement of Greenland; and geological indicators of paleoclimatic change were another key element, as he argued that the observed drastic changes of the climates linked to the shift of the continents relative to the poles. In short, Wegener marshaled evidence from very different domains to support his theory of continental drift.

Still, his theory wasn't accepted in his lifetime—not because it had gone unnoticed, rather the other way around: It got the attention of his colleagues, who mostly rejected it. Why was continental drift theory rejected by the scientific community in 1912 to be accepted only 50 years later? There are two general and different ways of explaining this phenomenon: rationalist and constructivist perspectives, both of which have provided frameworks for understanding this controversy.

The Controversy From a Rationalist Perspective

When trying to explain the controversy around the continental drift theory, many philosophers argue that although Wegener was right, the scientific community had legitimate reasons not to accept his theory. Some stated that Wegener had the general idea right, but he lacked enough

evidence to convince his colleagues. The main flaw would be an explanation of how the continents displace horizontally. This sort of evidence would come only 50 years later, with the discoveries that allowed Harry Hess to postulate the seafloor spreading hypothesis, which would serve as an explanation of the continental drift. This implies that Alfred Wegener had a privileged intuition that allowed him to recognize what was to become a correct theory but without the sufficient evidence to support it. This sort of characterization is summarized in the expression “being ahead of his time.” In that sense, Wegener is vindicated by these perspectives as an early advocate of an immature theory, “born at the wrong time,” or facing fierce opposition because he made a discovery before its correctness could be confirmed. At the same time, this explanation of the controversy covers in rationality the rejection adopted by Wegener's colleagues, as it would be a rational response not to accept a theory that lacks enough evidence.

Those points of view tend to explain the social acceptance of a theory by arguing that a theory gets accepted because it is true or because it is supported by sufficient evidence. But there are also rationalists who have perceived that many theories accepted in the past can today be considered incorrect, so the notion of truth maybe more unstable than is commonly supposed. Those rationalists may argue that theories are accepted because they offer more precise explanations than other available ones, or because they more completely solve those problems than others. Other who take this perspective believe that a theory can be adopted for its ability to capture the facts it chose to explain, its degree of generality, or its ability to focus on the things we are particularly interested in understanding. Ultimately, rationalist perspectives aim to explain the social acceptance of a theory by seeking an epistemic or cognitive element that supposedly holds the intrinsic superiority of that theory and induces the scientific community to accept it. The continental drift debate has been a fertile ground for those explanations, as many tried to explain the opposition that Wegener faced when he published his continental drift theory by arguing that it didn't provide enough evidence to be convincing. Others, within a similar perspective, explained the social rejection of the theory in terms of some

internal flaws or incompleteness, like the lack of a convincing explanation for the displacement of the continents. All of them consider that the scientific community rejected the theory in the early years of the 20th century because they had epistemic reasons to do so, and that the revised version of the theory under plate tectonics provided better epistemic elements (empirical evidence or more solid explanations) that forced the scientific community eventually to accept it.

The Controversy Through Constructivist Perspectives

A different approach to the acceptance of the continental drift theory has also been deployed, one more focused on the cultural and social contexts that shaped this debate.

One of the first implications that arise when looking at the cultural context of the debate is that the ideas about the displacement of the continents didn't start with Wegener in 1912, but long before. An early record of an advocate of the continental drift can be found in Abraham Ortelius, a 16th-century geographer, who included two central aspects of the continental drift theory: the continental fit and the movement of land masses. In his 1596 book, titled *Thesaurus Geographicus*, Ortelius argued that America had been torn away from Europe and Africa, and that the vestiges of the rupture can be seen from the complementarity of their coasts. The list of ancient proponents of the theory includes notable names such as Alexander von Humboldt, Francis Bacon, Comte de Buffon, François Placet, Thomas Young, Richard Owen, Jean-Baptiste Lamarck, and Antonio Snider-Pellegrini. All of them, among others, have proposed, with different degrees of depth, that the continents as they exist today once comprised a single continent, as can be inferred by the shape of their coasts as well as by such evidence as the similarities of the fossils found in the various continents. More closely contemporary authors to Wegener (but still before him) also developed continental drift theories, such as Frank Bursley Taylor, Roberto Mantovani, and William Pickering. The case of Taylor is revealing: By the end of 1908, this American geologist argued that, in the Tertiary period, the continents had moved

because of what he called *deforming forces*; 2 years later Taylor provided geological evidence in support of his theory. In earlier years, in fact, it was common to read about the *Taylor–Wegener hypothesis*, although later the name of Taylor was erased from the origins of the continental drift theory, jointly with the rest before him. Although Wegener provided an elaborated and developed notion of continental drift, the assumption that he should be considered the forefather of continental drift theory relies on the way geology as discipline constructed its own past in the 1960s, not on historical records of the pioneers of the theory. In any case, the idea that continents were not something fixed on Earth, but moving horizontally, was a persistent and recurring idea for centuries. These mobilist thinkers and scientists were opposing a dominant point of view, that of the fixists.

If mobilists conceived things to be in permanent change, fixists tended to believe that things had remained in the same place since the Earth's creation. At least until the middle of the 20th century, most biogeographers were fixists, as they considered that the positions of the continents had been relatively stable over the time scales. The extent, depth, and development of mobilists' theory could be very diverse, but there was always at least the idea of the displacement of the continents and some kind of evidence to support it. And they were always rejected by a majority of fixists. To reject is not simply to ignore, so they had to provide some answer to the arguments and evidence brought by mobilists. And they did. For instance, fixists managed to explain the similarities of the fossils that existed in different continents, arguing that the continents were fixed always to the same place, but also were once connected by trans-oceanic land bridges. While mobilists explained the existence of mountain ranges as the result of the crush of continents, fixists considered that the Earth was cooling and contracting from a previously molten state, like a baked apple coming out of the oven. For fixists, this contraction would explain the great mountain ranges all around the world. In every case, for fixists, it was impossible to conceive that the continents could move horizontally, and they denied the evidence and reasoning put forward by mobilists.

To view the debate around the continental drift theory as part of a broader cultural background that shaped it implies the recognition that these two styles of thought—mobilism and fixism—had coexisted for centuries, providing a general framework for the acceptance or rejection of the continental drift theory. There were many people before Wegener who had entertained similar ideas. Thus, Hess's ideas had their predecessors; for instance, he incorporated the idea proposed by Swiss geologist Emile Argand in the 1920s that mountain belts are created when two continents collide. Such ideas had a few supporters but also a lot of detractors. Although Wegener himself had some supporters, most of his colleagues rejected his theory. So what changed in the 1970s when the idea of continental drift was widely accepted? According to rationalists, some new evidence or perfected theory turned it irrefutable. But when Hess and his contemporary colleagues presented the plate tectonic theory, the scientific community didn't simply adopt it. By the middle of the 1960s, some prestigious scientists, such as Gordon MacDonald, J. Lamar Worzel, and Sir Harold Jeffreys, opposed the theory, disputed the new evidence, and labelled the plate tectonics theory as biased propaganda in favor of continental drift. In 1972, Paul S. Wesson collected 74 objections to continental drift and plate tectonics and concluded that the continents have never moved with respect to each other. Moreover, a survey of geologists, conducted in the 1960s and 1970s, revealed that those who already were convinced of the theory of continental drift viewed Hess's findings favorably, while those who were against the continental-drift theory rejected those same findings.

That the theory was eventually accepted may be attributable largely to social elements. Most likely, new generations of geologists, educated under the influence of mobilists who had attained positions of authority at the universities, accepted the theory just by inheriting the mobilist style of thought. Indeed, those who accepted late tectonic theory during the 1960s and 1970s were mainly young scientists. So in the end, most scientists did not surrender to some irrefutable evidence or reasoning; nobody changed their mind, but rather the change was due to a shift in social influences: mobilists increased the number of young followers.

The Importance of Plate Tectonics Theory

Plate tectonics theory is considered a fundamental scientific theory, capable of explaining most of the structural phenomena on Earth, such as earthquakes and the origin of continents. The idea of continental drift has acquired consensus among the scientific community, and it is used to explain not only the history of Earth landmasses but also the planet's evolution. The continents bordering the Atlantic Ocean, for example, are believed to be moving away at a rate of 1 or 2 cm (0.4–0.8 inches) per year. The European and North American plates are moving apart very slowly, but millions of years in the future, parts of California and Mexico will probably drift off to become an island. The emergence of new mountain ranges, islands, and associated earthquakes are possible to predict or at least to think, due to plate tectonics theory.

That Wegener had proposed a continental drift theory in 1912 without receiving any support from the scientific community has led to comparisons between the Wegener/plate tectonics situation and Gregor Mendel's being credited for discovery of genes. Published in 1866, Mendel's research was largely ignored until 1900, when he began to be seen as the father of genetics. This significant interval between the first presentation of the theory and its later acceptance is often explained as Mendel's being far ahead of his contemporaries' thinking. Similarly, many philosophers of science tend to explain that Wegener was ahead of his time, and that plate tectonic theory, proposed 50 years later, was more convincing. This sort of whig history (a historiography of science that assumes that rejected or ignored theories were just not as good as present-day theories, in a sort of linear progression of science) has placed all debates surrounding the acceptance of the theory as mere rational and epistemic issues. In a much subtler analysis of Mendel's laws of heredity, Augustine Brannigan considers that Mendel was not the founder of genetics nor was his contribution overlooked; he argues that the contexts in which Mendel's work was presented as well as its significance changed substantially over time. In a similar way of thinking, the

cultural background surrounding the long-term debate about the movement of the continents is what may have also changed, turning it finally into an acceptable idea, thereby enabling plate tectonics to develop.

In any case, plate tectonic theory is not only a fundamental scientific theory that explains many issues in earth sciences, but also an important historical case that enables us to understand what leads a scientific community to accept a theory, and when an idea comes to be seen as socially acceptable.

PRAGMATISM

Pragmatism, a philosophical movement often portrayed as U.S. America's leading contribution to the history of Western thought, originated in and around Harvard University during the late 19th century. The classical pragmatists include its founder Charles Sanders Peirce, its popularizer William James, and its key 20th-century representative John Dewey. Its main theoretical contribution is found with its use of the pragmatic *maxim*, a method or principle that emphasizes the clarification of theories, concepts, and hypotheses by establishing their connections to human practice and experience. With their discussion of the importance of practice, the pragmatists might be seen as largely hostile to theory. However, in both its classical and contemporary forms, pragmatism continues to contribute to theory in philosophy, education, sociology, and political theory. Although frequently critical of theory and its uses in philosophy, pragmatists generally seek an improved understanding of the relationship between theory and practice. In the process, they argue that the relevance of theory in its various formulations must be measured in terms of its practical consequences.

It was Peirce who first introduced the pragmatic maxim. James would notoriously adapt this maxim to his own purposes, leading to its most controversial formulation with the pragmatist theory of truth. Dewey's later experimentalism uses key pragmatist insights to argue for a rejection of any strict distinction between theory and practice. Among neopragmatists, Richard Rorty is the most famous for his general aversion toward the use of theory in philosophy. Recent work in political theory has looked to both Dewey and Peirce in the attempt to provide a defense of democracy that is grounded in pragmatist epistemology. As will be discussed in the following sections, these contributions are unified in sharing an epistemological perspective that is *fallibilist*, recognizing that any single belief could be in error, while looking to also clarify the norms that govern all forms of inquiry, stretching from the scientific to the moral and political.

The Pragmatic Maxim and Theory of Truth

Pragmatism emerged out of discussions between Peirce, James, and other like-minded intellectuals at what they called the *metaphysical club* in Harvard around 1870. Peirce further developed his contribution to these discussions in his publications during that period, but it was not until the turn of the century that James popularized the term *pragmatism* in public lectures. Both Peirce and James think of pragmatism as involving a method, principle, or maxim used to clarify concepts and hypotheses by linking them to their practical consequences. But they importantly differ in their understanding of the maxim and concerning how it should be applied in philosophy. Peirce insisted that his maxim be seen as a central logical technique required for progress within experimental science. Here, a statement is clarified when we list the experiential consequences we expect to occur if that claim is true. If one states that this diamond is *hard*, then this means that it will not be scratched by other substances. The concept *hard* has been clarified by indicating what practical effects we should expect to follow if that statement is true. This pragmatic degree of clarity is important for Peirce because of the central role in plays in inquiry. If our beliefs did not have any consequences, if their being true or false did not make any difference in our expectations, then the belief is empty from the standpoint of scientific inquiry.

James presents pragmatism as a method that helps to locate the significance of competing philosophical viewpoints and as a tool for highlighting empty verbal disputes. In his book, *Pragmatism*, he claims that the basic purpose of philosophy is to determine what difference the acceptance of one position would have at some specific point in our experience if this position were in fact true. Here, pragmatism is offered as a proposal, equipped with a method, which is justified through its fruitful application within the possible range of human experience. For example, he claims that the concept of freedom, once submitted to pragmatic standards, proves significant not through making actions morally accountable but because it allows for novelties in the world. The pragmatic meaning of freedom is located in

its promise for the possibility of improvement, something that we all count as a significant dimension of human life and experience. James is perhaps most notorious for his controversial remarks on pragmatism as a theory of truth. Here, he offers various formulations: the *true* as what is good for belief, truth as expedient for behavior, truth as what ideas become when they connect with other experiences and ideas as true instruments. These claims are open to both good and bad interpretations. They have been read by many critics as offering the untenable view that identifies truth with usefulness or the further surprising suggestion that a belief can be made true if it contributes to our happiness.

John Dewey's Experimentalism

In *The Quest for Certainty*, Dewey uses pragmatist ideas concerning the function of knowledge to criticize the strict separation between theoretical knowledge and practical judgment. He offers a historical diagnosis of the roots of this distinction, locating it in the Western tradition's philosophical pursuit of certainty. In response to the need for security in a perilous world, Greek thought held up the ideal of certainty as the ultimate measure of human knowledge. This view required that the objects of knowledge be fixed and unchanging and therefore something known independently of the changing environment that characterizes the arena of human practical activity. Dewey argues that this division between knowledge and action has been further preserved in modern thought, resulting in the view that beliefs about practical action are of less value than those achieved through intellectual theoretical pursuits. This separation between theory and practice has further resulted in diverting attention from addressing the practical problems of modern life.

Dewey further argues that this separation has been thoroughly rejected within the experimental perspective found in the procedures of modern scientific inquiry. He explores the profound changes in our conception of the theory–practice distinction that follows from the modern practice of knowing, illustrated within experimental science. Practical action should no longer be seen as inferior to theoretical knowledge, and the

commitment to security that is achieved through active control of our surroundings should be viewed as more important than any certainty found in theory. This does not result in the elevation of practice or action over theory. Rather, the important emphasis is on a deepened appreciation for the value of constant interaction between theory and practice. Dewey's pragmatic experimentalism takes both knowledge and practice as means for achieving goods and making them more secure within human experience. This further sets the main task for philosophy: Its function is to help encourage fruitful interaction between those beliefs arrived at through the most reliable methods of inquiry and practical concerns about those values, ends, and purposes that should direct human action and social life.

Rorty's Pragmatism as Antitheory

Rorty's controversial form of neopragmatism emerges from his critical analysis of the defining features of modern philosophy, where he focuses on dismantling the idea that knowledge involves the accurate representation of a world external to the mind. Taking inspiration from a nonstandard reading of Dewey, Rorty's pragmatism rejects its status as a theory of truth or meaning. Instead, he views pragmatism as denying the need for any epistemological or metaphysical view that would provide independent support for our human practices of deliberation and justification. For him, it more closely represents a critical attitude toward philosophical approaches that seek to justify claims in some type of grand universal philosophical theory. This does not amount to a rejection of the need for justification but of the view that our justificatory practices require additional validation from some independent philosophical source beyond them, as traditionally found in nature, God, or the mind.

This form of pragmatism, in its aversion to philosophical theory, further informs Rorty's political thought. Rather than seek philosophical principles that support democracy, he argues that our commitment to democracy has no need for such extra-philosophical support. This is based on his further controversial claim that the search for such support is incoherent, being based on an obsolete philosophical vocabulary. There are, he argues, no

external facts about human nature, reason, or morality that supply the needed foundation for democratic practices. Any defense of liberal democracy must then proceed from an acceptance of our historically contingent human practices of association and debate as the sole source of justification for those practices. Rorty's own defense of democratic ideals of freedom and justice will then hinge on descriptions of those practices that reveal their ongoing efficacy in addressing the practical political problems of our time and place.

Pragmatism and Democracy

John Dewey's view of the function of philosophy as addressing the conflict between scientific knowledge and human value resulted in the extension of pragmatist ideas into political philosophy and democratic theory. Recently, pragmatists have adapted Deweyan ideas in establishing an epistemic defense of democracy and democratic institutions. Others have been critical of this approach and instead look to Peirce for a pragmatist conception of epistemology that is capable of supporting a commitment to deliberative democracy.

This epistemic defense of democracy, whether in Deweyan or Peircean form, contains three main elements. First, it stresses the importance for democratic decision making of processes that ensure open public debate where citizens can offer information, distinctive viewpoints, and arguments. Second, it offers an epistemic defense of this decision-making process. Collective decision making is here presented as improving the results of this discussion; and acceptance of its outcomes is, at least, partially explained by its value for knowledge acquisition and problem-solving ability. Finally, this view gives a distinctly pragmatist account of the view of knowledge that underlies this deliberative process.

The neo-Peircean version of this view looks at the function the concept of *truth* places in our cognitive lives. Having a belief is to believe that a specific claim is true and to further accept that it would remain undefeated by the future course of experience and human inquiry. Being responsive to evidence, experience, and reasons is here taken as a *constitutive* norm of belief, meaning that it is part of the very nature of a belief that it be

sensitive to reason. This norm further points to the social nature of inquiry. Aiming at the truth requires that we test our beliefs against the available evidence where this involves the social practice of articulating and defending one's views to others. Seeking truth then demands that believers participate in the community of inquiry. Reflection on the nature of belief leads to the need for further inquiry involving community wide participation.

A commitment to deliberative democracy then emerges out of basic epistemic presuppositions of Peirce's pragmatist view of knowledge and belief. Having beliefs commits one to interpersonal norms of communication and discussion, where these further require recognizable democratic values such as freedom of speech, open debate, diversity of perspective, accountability, and openness to revision and change. If this type of inquiry is to function effectively, a further set of democratic institutions are needed to support forums for such deliberations, including the necessary feedback mechanisms in the form of periodic elections and a free press. It remains an open question whether this Peircean perspective can yield an adequate defense of democratic norms and institutions on the basis of such minimal epistemological resources.

PREDICTION

When faced with uncertainty, people from time immemorial have turned to prophets, seers, shamans, oracles, or clairvoyants to answer the urgent question “What will happen?” and the closely related question, “What shall we do?” Today, the responsibility to make predictions falls mainly to science. Scientists can inform about the future not because they possess some secret information about what happens next, but because science is able to reveal regularities and laws of nature. The term *prediction* refers to a variety of phenomena and tasks, including making weather forecasts, estimating the long-term effects of rising levels of greenhouse gas emissions, projecting election results or the effects of political reform, informing business planning, evaluating the market potentials of new products, or forecasting the outcome of scientific experiments. In contrast to *prophecy*, prediction is based on reliable method and equally reliable data: meteorological time series, annual reports, survey data, or the results of experimental investigation provide the basis for informed knowledge claims and allow for reasonably assuming regularities and continuities.

One of the most contested issues today is the influence of *big data* on the quality of scientific prediction. In recent years, improvement in information collection and information processing technologies has dramatically increased the availability of data. What remains to be seen is whether this development will lead to an exponential growth in scientific knowledge and contribute to the accuracy of scientific prediction, or succumb to the danger that relevant signals will get lost in the steadily growing noise of meaningless data.

In science, generating a hypothesis means to make a prediction. In general, predicting implies the making of well-founded statements about a specific phenomenon before it can be observed. This implies that a prediction must be more than an educated guess. Predicted outcomes must either be certain or (at least) be assumable with a sufficient degree of probability. Seemingly, predicting is not only about future knowledge, or knowing in advance, but also about matters not already known. In scientific contexts, this often refers to the capacity of a theory (or set of theories) to

predict specific outcomes, thus indicating the quality of a theory. Moreover, the significance and meaning of predictions in science differ between the opposing epistemic perspectives of deduction and induction. Furthermore, the relevance and reliability of scientific prognoses vary between probabilistic (stochastic/statistical) and full explanations (applying for all cases under all circumstances).

Finally, prediction has different meanings in the natural and in the social sciences. In the first case, predictions are correct epistemic claims on the basis of well-established and empirically confirmed theories. The inherent risk of making predictions in the *natural sciences* is fallacy. If the theoretical assumptions are incorrect and/or the data corrupted, the wrong conclusions will be drawn. In reverse, if a particular outcome predicted on the basis of a specific theory fails to materialize, then the quality of data (and observation) and/or the correctness of theoretical model must be reviewed.

In the *social sciences*, prediction is at the same time more difficult and much riskier. Social sciences deal with specific historical cases. Extrapolation from the data gathered and analyzed in a particular case is difficult because scientific laws in the social sciences differ from those found in the natural sciences. Moreover, because of the responsiveness of the very object of research (the social world) to scientific findings and claims, statements given in the social sciences can have an effect. Description can turn into prescription. In contrast to the natural sciences, the correctness of predictions in the social sciences not only depends on the proper application of theoretical models and the sound interpretation of empirical data but can result from the interplay between the scientists making the claim and their audience. This problem of potential *self-fulfilling prophecy* is a cardinal conceptual problem and a major obstacle to scientific prediction in the social sciences.

Explanation and Prediction From Deductive and Inductive Perspectives

Scientific explanation in general is based on regularities. This implies that a specific explanation

does not apply for a single event or phenomenon but can be hold true for all cases within the same category. Instead of explaining why a particular apple falls from a specific tree, the theory of gravity seeks to offer a credible explanation that applies to all apples (and all other objects with mass). The claim of modern science to uncover regularities and discover (universal) laws implies a claim to the capacity to predict certain events: If, on the basis of available data, a universal law can be derived, then this law should apply for all unobserved and future cases as well. *Because* until now all objects of the type *a* have under the circumstance *b* behaved in the way *c*, the same behavior can be predicted for this particular class of objects under the same circumstances.

In principle, two fundamentally different perspectives of scientific reasoning can be distinguished: deduction and induction. *Deduction* seeks to subsume specific cases under some general scientific laws and derive an explanation of a particular event by proving that it is an instance covered by a (set of) empirically proven regularities. *Induction*, in contrast, aims at coming to a general conclusion by observing single, individual instances. Both approaches are problematic from the perspective of the philosophy of science, especially with regard to their predictive power.

Deductive explanations have a strict logical form. It can be expressed employing the deductive-nomological model of explanation introduced by the German-American philosophers of science Carl Hempel and Paul Oppenheim. The model consists of the *explanans* (the general laws and particular facts that actually do the explanation) and the *explanandum* (the phenomenon that should be explained). The explanandum must be logically deducible from the explanans in order to satisfy the requirements of the deductive-nomological model of explanation. In the famous paper from 1948 titled "Studies in the Logic of Explanation," Hempel and Oppenheim argue in favor of a logical symmetry of scientific explanation and prediction. In general, the logical structure of the deductive-nomological model can be expressed as follows:

Explanans: The general laws of gravity tell that objects with mass fall to earth in a straight line. Apples are objects with a mass.

Explanandum: A particular apple falls to earth in a straight line.

According to Hempel the deductive-nomological model not only explains the trajectory of a falling apple but also allows for predicting apples to fall. In his view, explanation and prognosis are closely, logically interrelated: In the deductive-nomological model every explanation is a potential prognosis and vice versa. This is called the *thesis of structural identity*. Because in the deductive-nomological model the explanandum is logically implied by the explanans, the model can be used to formulate predictions with reference to the explanandum. The formalism of the deductive-nomological model of explanation and, in particular, the strict rules for scientific explanation render logically irrelevant the difference between (a) an explanation of cases already observed and (b) a prediction with regard to the outcomes of similar but unobserved cases. Because every scientific explanation requires the proof that a particular case (the explanandum) is covered by assignable laws and regularities, the explanation for similar cases can be given in advance of the actual observation. In reverse, the formulation of a prediction on the basis of established theories bears the risk of falsifying this particular theory or set of theories. The principle of *falsification* is a concept that demands scientific theories to make some definite predictions testable against empirical evidence. According to the Austrian philosopher of science Karl Popper, noted for his advocacy of this principle, risking falsification is both a necessary element of scientific progress and a reliable criterion for distinguishing science from pseudoscience. From this perspective, falsifying a scientific prediction proves the underlying theoretical concept wrong. Similar to Hempel and Oppenheim, he assumed a symmetry between scientific explanation and prediction. The value of prediction is primarily epistemic, for every explanation can in principle be expressed as a prediction. In this sense the deductive-nomological model of explanation offers a comprehensive but specialized framework for scientific prediction. Predictions can either be correct or not. If we can subsume a particular phenomenon under a class of cases for which deductive explanation have been found reasonable, then predictions can be made. Because the deductive-nomological model requires

the laws expressed in the explanans to cover all cases with specific conditions (e.g., there must be no exclusion from the universal law of gravity for any objects with a mass), the only difficulty is to determine whether a particular phenomenon is part of a larger class of cases. Probabilistic prediction ("it is highly likely that x ") is just as doubtful as prediction with regard to a phenomenon for which no general explanation is deducible.

In a sense, probabilistic explanation and prediction touch upon the core of inductive reasoning. In the case of predictions made on the basis of probability, correctness is a prime virtue, too. However, in drawing on the principles of inductive reasoning, they should be measured against the touchstone of accuracy. In contrast to explanation derived deductively, inductive reasoning starts with premises about cases already examined to draw conclusion about cases which have not yet been observed. Induction can be described as a bottom-up approach of scientific reasoning aimed at making generalizations on the basis of a finite number of observations. The observation of a number of falling apples n leads to the conclusion (prediction) that the next apple one might observe (n_{+1}) will behave in the same way. However, inductive reasoning poses some serious logical problems for making predictions. The cardinal problem of the inductive perspective is how to logically justify the assumption that the regularities or (presumed) causal relationships found in observed cases will persist into the future. How can particular outcomes of unobserved cases be predicted without referring to universal, covering laws?

From a logical point of view, prediction made on the basis of inductive reasoning is necessarily rendered preliminary and uncertain. This can be illustrated with reference to the *black swan problem*. Inductive reasoning rests on the assumption that one can arrive at general statements or a conclusion by making a series of singular existential statements based on observation. For instance, initial observation can reveal that a specific type of bird (a swan) is white. Subsequent observation of a number of swans may confirm this finding. As stated above, there is no logical argument for assuming that *all* swans are white since the discovery of a single black swan would falsify the conclusion. However, it may be possible that black swans are rare, so that the probability to correctly predict the color of swans is still very high. But how can

this belief in high probabilities of drawing the right conclusions be justified?

The 18th-century philosopher David Hume, noted for his work on inductive reasoning, was convinced that expectations about unknown cases are primarily determined by custom, understood as a subjective psychological disposition. Hume therefore offers a psychological explanation for the underlying mechanism behind empirical predictions: custom and habit. His explanation claims a lack of rational logical justification for this mechanism. The same is true for his *uniformity of nature* assumption, which develops this argumentation even further. It functions as a presupposition for inductive reasoning in general. The uniformity of nature assumption implies the fundamental belief that the natural world is guided by regularities (unobserved cases, which are in all relevant aspects similar to cases already examined, will be similar with regard to the conclusion). However, the truth of the uniformity of nature assumption itself cannot be proven. Ultimately, inductive reasoning for Hume rests on *good faith* rather than on logical principles. Therefore, inductive explanation and prediction always contains subjective elements (customs and degrees of conviction).

Although neither probabilistic prediction nor predictions based on inductive reasoning can attain definitive certainty, the plausibility (accuracy) of such predictions can be increased. Especially the Bayesian conception of subjective probability offers formal rules and procedures for enhancing the reliability of such predictions.

Prediction, Probability, and Bayes' Rule

Scientific prediction as well as scientific explanation can be based on probabilities (e.g., stochastic calculation and laws based on statistical connections). However, the concept of probability causes difficulties in science. First and foremost, the term itself can have different meanings. From a statistical point of view probability is closely linked to frequency. Scientific findings may indicate that in eight out of 10 cases y is the result of x . Therefore, the probability to predict y to be caused by x is 80%. The frequency interpretation of probability is unproblematic as long as it is based on actual (countable) evidence. It becomes more difficult

when based on proportions or relations alone. Given the vast number of solar systems in the universe, it is highly likely that a large number of planets similar to earth exist. Although it is probable that a number of those planets have suitable conditions for organic life, it is not possible to calculate the likelihood of extraterrestrial life or statistically predict its existence with the same degree of confidence as in the initial example.

Next to the frequency interpretation of probability are subjective assessments of probability. The subjective probability of a proposition expresses the degree of belief or credence of the researcher. This does not imply that subjective probability has to be arbitrary. *Subjective probability* rather refers to nonobserver-independent probability. In the scientific context, subjective probability is based on theoretical assumptions and existing evidence. Hypotheses, which include propositions based on subjective probability, refer to the presumed likelihood assigned to a hypothesis given the current state of knowledge. Accordingly subjective probabilities can—in line with the principles of inductive reasoning—be adjusted when new evidence becomes available. Using the Bayesian approach to probability can provide the need for rules how this adjustment could actually be made.

This approach, now among the most prominent interpretations of subjective probability, is named after 18th-century mathematician Thomas Bayes. He provided a formalized, machine-like procedure to evaluate the probability of a hypothesis. At the beginning the prior—that is, the subjective—probability of a particular hypothesis before any evidence is considered has to be defined. Additionally, the *posteriori* probability has to be set. *Posteriori probability* refers to the subjective probability immediately after relevant evidence came in. For calculating posteriori probability given defined prior probabilities, Bayes developed a formula for relating the (prior and posteriori) odds of event X_1 to X_2 conditioning on event Y (*Bayes' rule*). The relationship between the odds of X_1 and X_2 to Y is called the *Bayes factor* or *likelihood factor*. Sequential use of Bayes' rule (with posteriori probabilities of in the first round become priors in the second) offers a structured approach for systematically take evidence into account. Bayes interpretation of probability allows calculating changes of subjective probability in the light of (new) evidence.

The Bayesian approach provides standards for linking prior and posteriori probabilities and contributes to improving the quality of probability-based prediction. However, it is not possible to eliminate the subjective element altogether. It is therefore not possible to objectify subjective probabilities and degrees of belief in a way that the general certainty deficit of predictions based on induction could be solved.

Epistemic and Empirical Significance of Scientific Prediction

Prediction is generally understood as an informed statement about an unobserved phenomenon (x will occur). Against the background of fundamentally different approaches to scientific reasoning, and given difficulties of including probabilistic statements in scientific prediction, it is important to further distinguish between the epistemic and empirical significance of predictive propositions. As was demonstrated earlier, making correct predictions can be instrumental in testing the validity of general scientific laws. Therefore, in the perspective of deductive reasoning prediction is of epistemic significance, proving that the outcomes for a particular case (explanandum) were contained in the explanans. Making correct prediction also helps, when Bayes' rule is followed, to enhance the plausibility of subjective probability estimation, which forms the starting point of inductive reasoning. Making predictions from both perspectives has an important though somewhat different epistemic value. An important question, and ground for a continuing debate within the philosophy of science, is whether scientific theories must be able to make successful novel predictions. While this debate mainly focuses on questions of the nature of novelty (Should it be understood in a temporal sense only? Or should phenomena previously impossible or improbable to predict be included?), another line of the discussion is about confirming novel predictions, thus directly touching upon the empirical significance of prediction. From a deductive perspective, confirmation must take place within the logical structure of the deductive-nomological model. A true novel prediction eventually confirms that some known, general laws and regularities cover a particular, unobserved case.

Confirming prediction made on the basis of inductive reasoning and probabilistic statements means to enhance the probability to make correct statements by including relevant empirical evidence. Whereas the Bayesian rule provides procedures for the structural inclusion of such evidence, selecting and interpreting empirical findings pose some major methodological and epistemological challenges.

Prediction, Empirical Evidence, and Laplace's Demon

How to actually make empirical predictions? From the perspective of scientific determinism, the quality of a prediction depends on the complete knowledge of the underlying principles and laws as well as the inclusion of all relevant empirical data. When this knowledge is available, precise predictions can be made. The in-principle predictability of unobserved cases given complete knowledge of past and present states is frequently referred to as *Laplace's demon*, after 18th-century mathematician Pierre-Simon Laplace. As a thought experiment a supernatural entity (the demon) with complete knowledge (including the precise position and motion of every atom in the universe as well-secured information concerning the underlying laws) must be capable of correctly predicting all of their future conditions and so the state of the future. This argument is called *scientific determinism* and rests on the assumption that every state of affairs (including human action) is the inevitable consequence of previous events that are related in a regular manner. According to this view, the quality of predictions can be improved by adding further knowledge (empirical information or secured scientific knowledge about laws and regularities). Although scientific determinism has a strong appeal to the natural sciences, it is frequently criticized from the perspective of the philosophy of social science. One strand of criticism, which may be called the *pragmatic argument*, doubts the possibility of having complete knowledge of human action. For human action includes a large number or (potentially interacting) variables, such as psychological conditions, motivation, and belief systems. Therefore, it is impossible to gather sufficient knowledge. A second and perhaps more important strand of criticism aims at the deterministic belief in necessarily connected event

chains: Assume that one has complete knowledge including all empirical data and underlying laws relevant to a particular case at a given moment in time (t_n). Scientific determinism states that the conditions which led to the state t_n are the necessary consequences of previous events $t_{<n}$. From this perspective it would be possible to continue the chain of events to arrive at complete knowledge for a future state of affairs t_{n+1} . The question, and primary cause for criticism, is whether this is true for social developments. The state of affairs at t_{n+1} could be anticipated at t_n . Since the condition at t_{n+1} are (partially) the consequences of human action, and these actions are in turn premised on anticipations, the consequences of these anticipations (expressed in predictions about future states of the social world) manifest in the future state of affairs. This leaves unanswered the question whether the anticipations contain knowledge about inevitable developments or whether they are actually *causing* specific developments.

Prediction in Social Sciences: The Thomas Theorem and Self-Fulfilling Prophecy

The complexity and contingency of the social world are generally referred to in order to explain the relative predictive weakness of the social sciences. From the perspective of scientific determinism, it is particularly hard to arrive at sufficient (let alone complete) knowledge about social cases. The predictive power of the social sciences is seen as limited by insufficient methods of data ascertainment and analysis, and by qualitative differences between empirical evidence in the natural and the social sciences. In the natural sciences, empirical evidence provides information about what is the case. In the social sciences, evidence rather discloses what makes the case. This fundamental qualitative difference is summarized in the so-called *Thomas theorem*: If men define situations as real, they are real in their consequences. In the social world cases cannot be reduced to their objective features. Social action is always—and at times primarily—determined by the meaning of a particular situation. This poses a major problem for making predictions. For predictions in the social sciences not only run the risk of missing relevant knowledge but also affect

and alter the meaning of a given situation. The mechanisms and dangers behind this problem were illustrated in a classical text on self-fulfilling prophecies by sociologist Robert K. Merton, taking the example of a bank run: To issue a warning concerning the liquidity of a financial institution, economic research, including the analysis of accounting reports and balances, should reveal reliable data to justify the warning. Correct interpretation of available evidence allows anticipating financial turmoil and helps investors and savers to prevent losses. Based on scientific examination the warning can either be justified (supported by correctly interpreted evidence) or not. With reference to the Thomas theorem, Merton argues that scientific predictions (in this case the warning of bankruptcy) can be instrumental in causing the described effect. When investors and savers learn about the warning and rate it as trustworthy, they will act *as if* the warning were well founded. As rational agents they will pull out saving deposits and sell their stock at fire-sale prices, eventually causing the very liquidity problems they are trying to escape. With reference to the logical status of prediction in the social sciences, the relation between describing specific developments and creating or facilitating certain changes is highly problematic. This problem touches upon a major question and primary source of dissent in the social sciences. Can social sciences make predictions in the same way the natural sciences do?

Besides mentioning logical and epistemological restrictions, Karl Popper highlighted this question when he launched a general attack on historicism, formulating a fundamental criticism of the role of prediction and prophecy in the social sciences. *Historicism* refers to the doctrine that social sciences have the task of making historical prophecies (analogous to predictions in the natural sciences) and that these predictions are necessary to conduct politics in a rational way. Popper criticizes historicism and in particular the theoretical flagship of his time, Marxism, for being nonscientific and violating the methodological principles for making scientific predictions. Popper identifies two constitutive (sub) doctrines of historicism: (1) the historicist doctrine of social science, claiming that social sciences should make historic predictions about social developments (e.g., predicting

social revolutions) the same way that natural sciences make predictions about natural phenomena (e.g., solar eclipses); (2) the historicist doctrine of politics, which assigns the task of facilitating these developments to politics.

The first of these two doctrines is criticized for being methodologically untenable. Long-term *prophecies* (or predictions) can only be derived from conditional predictions (asserting that certain changes will be accompanied by others). Additionally, in line with the deductive-nomological perspective of scientific reasoning, in order to make certain (long-term) predictions, the superordinate system must be well isolated, stationary, and recurrent. Social systems, in contrast, are interdependent, dynamic, and at times produce original, unparalleled configurations. Predictions of social developments (e.g., revolutions) therefore are not only less certain but also cannot be derived from universal social laws. Because the objects of research (societies as a whole; specific groups like the middle class) are, according to Popper, more postulates of social theory than empirical objects; and since social change and societal development are not necessarily the result of deliberate design but can be the unintended consequences of intentional action, instead of making historical prophecies (which, in line with the second historicist doctrine, allow the provision of political roadmaps to ease inevitable developments), social sciences help to understand the possible consequences of human action. Hence, it is impossible to predict the necessary revolutionary development eventually leading to the overcoming of capitalist order with scientific certainty as Marxists intended to do. It is also impossible to formulate the necessary political accompanying measures to facilitate this development. Social sciences are nevertheless practically important. By analyzing the interplay of aspects of the social world (e.g., the consequences of normative concepts like *gender equality* for productivity and the formal organization of the labor market or economic principles of growth and the problem of externalization for environmental protection), social scientists are able to identify likely consequences, issue warnings of risks, and help political decision makers and societies in general to shape political programs. However, given the nature of societies and in particular the interplay of intentional action and unintended consequences, social sciences are limited to make probabilistic statements

(implementation of policy x is likely to have the effect y). Moreover, as the addressees of the findings of social sciences are able to interpret and interact with them, the danger that such statements will affect the probability of their being correct (turn out to be self-fulfilling prophecies) remains.

Empirical Prediction and Big Data

Big data (also referred to as *data science*) is a generic term for the increasingly available and evaluable large data sets. Improvements in data storage and processing capacities, along with new and advanced options in digital data collection, seem to be giving rise to Laplace's demon. Ranging from national economic statistics, communication reports, social media networks, and meteorological data to global positioning tracking, vast amounts of data on virtually all aspects of life have become available. With the empirical basis for prediction increasing, does this imply that the quality of scientific prediction increases accordingly? This question cannot easily be answered. The impact of information on the quality of scientific predictions depends, on one hand, on the quality of data itself and, on the other hand, on a proper understanding of the underlying principles and interdependencies. Whereas the first aspect refers to the crucial need to filter signals out of the rapidly swelling noise of context (i.e., to separate relevant from irrelevant information), the second aspect points toward the priority of useful criteria for this selection process.

Additional evidence can thus help to increase the plausibility of the subjective calculation of probabilities following Bayes' rule. Additionally, a growing number of observations increases the reliability of statistics based on frequencies. It is therefore plausible to expect advancement with regard to the correctness of empirical observation based on (relatively) simple theoretical models. To a certain degree, this is also true for empirical estimation based on highly complex data, as in weather forecasting. Although the fundamental relationship between key variables influencing the development of local weather phenomena are known, and additional data and time series improve the reliability of forecasting models, the system's complexity sets limits to the accuracy of the predictive efforts. Turning to complex

question where the underlying principles are not fully understood, the increase in available information actually can diminish the predictive power. With reliable criteria to distinguish *signal* from *noise* lacking, the risk of using irrelevant information rises considerably. Obviously, it is not the sheer amount of available information that determines the quality and reach of scientific prediction. Even with computational capacities increasing equally, the simple equation of more (information) = better (predictions) cannot be sustained. The increase in data availability conjures up a mentally impaired Laplace's demon unable to make sense of a vast amount of information. Without suitable theoretical assumptions for selecting relevant information, and lacking a working hypothesis about the connection and the phenomenon in question, the "garbage in, garbage out" principle will thwart possible improvements of increased information availability. This principle, borrowed from the field of computer sciences, refers to the fact that computational capacity cannot replace scientific theory development. For computers will process any (including nonsensical) data (garbage in) and will use programmed algorithms to produce respective (including nonsensical) output (garbage out). In consequence, big data will not automatically increase the predictive capacities of scientific inquiry. Improvement in data availability will only have an added value for scientific research and scientific prediction if the suitable theoretical models can be developed.

Dealing With Probability and Uncertainty: Forecast Models and Scenarios

What separates scientific predictions from prophecy? What are the principles of scientific forecasting? As stated above, distinct principles and perspectives of scientific reasoning assign specific epistemic and empirical values to predictions. Moreover, differences between the social and the natural realm reveal problems of scientific determinism and set limits to scientific predictions in both scope and accuracy. Finally, the increase in data availability and the advent of big data can enhance predictive power only when suitable scientific theories and methods are at hand.

As noted earlier in this entry, scientific predictions differ from prophecies by relying on models and methods. Reflecting the differences between natural and social sciences and distinct perspectives of scientific reasoning respectively, predictive methods can be categorized with reference to their primary objectives. From the perspective of deduction, predictions are made to test specific theoretical assumptions. The selection of methods for testing hypotheses and making predictions is determined by the respective epistemic goals. In the last four decades, an extensive set of quantitative and qualitative methods has emerged for making empirical predictions, complementing more traditional approaches of making predictions to test scientific hypotheses. Among the most prominent methods are (computational) modeling, especially relevant to climate science and meteorology, cross-impact estimation, which aims at calculating the co-occurrence and impact of events on the basis of conditional probabilities (predominantly used to predict the interplay of natural and societal change); scenario planning (a widely used technique, which arguably draws lessons from Popper's critique of historicism by avoiding *historic prophecies* and modeling plausible developments instead); and qualitative approaches like the Delphi methods (relying on expert opinion to improve subjective probability calculation).

A textbook example for replacing old (nonscientific) methods of predicting is weather forecasting. We need not go back to ancient or medieval times, when people attempted to predict the weather by interpreting signs and omens; rather, we can use the rise of quantitative weather prediction as a result of an increased demand for military meteorology since the 1920s. It was the demand to provide reliable weather forecasts for the emerging air forces during this time that triggered major changes in the science of meteorology. The production of weather maps, numerical modeling, and simulations were developed as a means to systematically include statistical evidence and improve the probability of occurrence (in accordance with Bayes' rule) in weather forecasts. The significance of computational models has further increased. In general, models are simplified representations of the world, which allow measuring and testing the influence of variables. They are particularly useful when the initial object of study (weather or climate systems) is too complex for

direct measurements. Because they allow testing the influence of specific variables repeatedly, they contribute to increasing the quality of estimating the subjective probability of a given variable to exert an influence. The aim of scientific modeling is to build sufficiently accurate models to allow useful predictions about the real world. Consequently, models can be good or bad.

Scenario development, in contrast, does not aim at providing an altogether accurate representation of the real world. Scenario development does not serve to eliminate uncertainty but rather to deal with it. Instead of feeding empirical information into a simplified model to measure the impact and interdependencies of single variables, scenario development aims at developing plausible narratives, laying out alternative ways of how the future might unfold. Accordingly, it is frequently used for strategic (economic and political) planning, as well as to explore the interplay of specific hazards and potential solutions (e.g., IPCC climate scenarios). Scenario development is frequently used to bridge the gap between findings and predictions (based for example on computational modeling) in the natural sciences and consequences for the social world. The scenario development process starts with the identification and assessment of *driving forces* relevant to a specific question. Additionally, time horizon and geographical scope (e.g., global carbon emissions, mitigation and adaption potentials by 2050) are specified. In keeping with Popper's critique of historicism, a number of scenarios (taking into account varying intensities or interrelationships of the driving forces) are being developed to present the possible connections and associated risks and to outline optional courses of action.

Computational modeling and scenario development are only some of many examples of the emerging field of futures research methodologies (a more comprehensive overview is outlined in the futures research methodologies handbook of the Millennium Project). Common to all methodological approaches is the need to conform to scientific standards. To make empirical predictions, methods need to be developed for the systematic selection and analysis of relevant data. To separate scientific prediction from prophecy, predictive methods

should consider the requirements and limitations of the opposing perspectives of scientific reasoning and the differing epistemic and empiric significance of predictions in science.

Prediction in Science, Prediction in Society

Prediction is an ambiguous term. This ambiguity derives from two sources: First, within science, predictions are of epistemic value, made to test hypotheses and be informative about the quality of theoretical models and assumptions. To make empiric predictions requires compliance with certain scientific rules (mainly for including and interpreting new evidence and calculating probabilities) and respecting the limits of predictive power (in particular in the social sciences). Second, these epistemological and methodological concerns at times conflict with the social demand for scientific advice. Science must of course make useful contributions to identify and deal with the challenges of the future. Predictions clearly are more than epistemic tools or empiric products of scientific research. They have effects in the social world, can provide desired or unwanted information, issue warnings, and inform about possible courses of action. As many observers have pointed out, it is crucial for science in general to maintain the distinction between scientific prediction based on theoretical assumptions and respecting clearly defined rules and methods, on the one hand, and prophecy the other. Prediction, as we have seen, is a scientific enterprise stemming from the desire to expand the frontiers of knowledge (either by testing hypotheses or by making accurate empirical predictions on the basis of theoretical concepts and models). Prophecy, in contrast, is a political enterprise making knowledge claims about unknown facts and the future without disclosing the processes and methods of how this particular knowledge was acquired.

believe the world was created by God less than 10,000 years ago, defend what they call *creation science*, arguing that it should be taught as an alternative to mainstream science in public schools. Practitioners of homeopathy, the treatment of disease by minute doses of natural substances, claim that their field is a science, and (often) that it should be a form of publicly recognized (and funded) health care. Climate-change skeptics also produce evidence that purports to be scientific, arguing that such evidence undermines the consensus view of climate scientists. If we are to resist such claims, we would appear to need some way of distinguishing genuine science from what merely appears to be science. What better term for the latter than *pseudoscience*? This entry presents the definitions and conventions that support the distinction and explores the basis of the various critiques and defenses that have arisen within the communities of practice and scholarship in which these issues are contested.

Critics of the Distinction

Despite its apparent utility, the term *pseudoscience* has fallen upon hard times. Many historians and philosophers of science have questioned whether any principled and consistent distinction can be made between science and pseudoscience. The most radical of these critics suggests that the distinction resembles the border between two nations that share a common landmass. In itself it is arbitrary, reflecting nothing more than the conventions by which it is established and the interests of those who support them. On this view, one can describe the ways in which people *distinguish* between science and pseudoscience, but the distinction has no normative significance. It tells us something about the people labeling the practices in question, but nothing about the practices themselves. In particular, it does not correspond to a distinction between reliable and unreliable ways of attaining knowledge.

A second form of criticism takes a more moderate line. It does distinguish between reliable and unreliable ways of attaining knowledge but argues that these are not captured by the terms *science* and *pseudoscience*. This view was made famous in a 1983 essay by Larry Laudan who argued that

PSEUDOSCIENCE

The terms *pseudoscience* appears, at first sight, to be a useful one. Science is widely regarded as one of our most dependable ways of forming beliefs about the world. It may not answer all questions, but the questions it does answer, it answers with a high degree of precision and reliability. But there are those who claim the mantle of science—piggybacking, so to speak, on its reputation for reliability—whose credentials for doing so are dubious. Some young-earth creationists, who

attempts to distinguish science from pseudoscience have repeatedly failed. Early efforts at making such a distinction focused on method, assuming that there was a single scientific method. But this assumption has been shown to be false. Later attempts focused on the criterion of verifiability or falsifiability, the latter made popular by the work of the philosopher Karl Popper. A scientific theory was one that could be shown to be true, or (on the Popperian view) shown to be false. But many practices we may think of as pseudoscientific are eminently falsifiable. The efficacy of homeopathy, for instance, is testable by way of randomized trials. So this criterion also fails. Laudan is keen to distinguish between reliable and unreliable cognitive practices. But with regard to the term *pseudoscience*, his conclusion is very similar to that of the more radical critics: It is an empty term, of merely rhetorical significance. Since it does no useful work, it should be abandoned.

Defenses of the Distinction

So useful is the distinction, however, that it has not gone away. Recent attempts to defend the distinction between science and pseudoscience have involved two moves. A first move has been to broaden the scope of the discussion, from beliefs, propositions, or theories to the social practices that produce them. A second move has involved producing multifactorial accounts of what distinguishes science from pseudoscience. On this view, our knowledge-producing practices fall on a spectrum, from the clearly scientific at the one end to the clearly nonscientific at the other. When practices at the nonscientific end of the spectrum claim to be scientific, they may rightly be labeled as pseudoscientific. On this view, the distinction between science and pseudoscience is not identical with that between reliable and unreliable cognitive practices. Practices we term pseudoscientific may enjoy some degree of reliability. But they lack the particular kind of reliability associated with science.

Practice-Based Accounts

A first move in the defense of the category of pseudoscience is to clarify just what it is we are distinguishing. Early discussions tended to assume

that what had to be labeled as either scientific or pseudoscientific were propositions or theories or perhaps methods of inquiry. But more recent studies of science have made it clear that science is a social practice: a collective activity that has a goal and is governed by norms. The reliability of scientific inquiry is not simply a matter of methods of inquiry employed by individuals; it also depends on interaction with others. It relies on other people to provide a starting point for inquiry, to replicate experiments, and to review and interpret results. More precisely, science is a particular kind of practice: It is a variety of cognitive practice, one devoted to the attainment of knowledge. Cognitive practices do, of course, give rise to propositions and theories. But if we are to understand the difference between science and pseudoscience, we should not begin with propositions and theories. We should begin by examining the character of the *practices* from which propositions and theories emerge.

Not all writers who make this point do so by speaking of practices. Mario Bunge, for instance, speaks of *cognitive* or *epistemic fields*. But the elements that make up an epistemic field include a research community pursuing a certain line of inquiry. So this view also recognizes that science is a collective activity. By focusing on the structure of this collective activity, we can employ a wider range of criteria than would be available if we focused merely on propositions, theories, or individual methods of inquiry.

Multifactorial Accounts

This insight leads to the second move in the rehabilitation of the category of pseudoscience. Early efforts to distinguish science from pseudoscience sought to identify a single factor (such as falsifiability) that would mark off the two domains. But it has become clear that while each proposed criterion may have some value, no one criterion will suffice. For any one such criterion, there will be pseudosciences that meet it and fields that appear to be scientific that do not. (Young-earth creationism is falsifiable, for instance, whereas string theory arguably is not.) There *are* criteria that we can use in making such judgments, even if no single criterion among them is sufficient to allow us sharply to demarcate science from

pseudoscience. But they will allow us to say that a practice that purports to be scientific lacks a number of the characteristics of a science.

What kind of criteria should we employ in making such judgment? They should be criteria that have epistemic significance: features of scientific practice that account for its particular kind of reliability. We can zero in on such features by thinking, first of all, about the characteristics of an ideal epistemic community, one whose procedures are most likely to eliminate error and encourage the pursuit of truth. We can then identify further features that single out scientific practices from those of other epistemic communities.

Perhaps the most famous attempt to identify the features of an ideal epistemic community comes from the work of the sociologist Robert Merton. Merton identified four norms that he believed characteristic of scientific communities. The first is what he called *universalism*: Factors such as race, nationality, religion, gender, and class are considered as irrelevant in the assessment of practitioners' work. The second is what Merton calls *communism* (or, if you prefer, *communalism*): the idea that the results of inquiry are made freely available to all. Merton's third norm is *disinterestedness*. Although individual scientists may be far from disinterested, the scientific community has procedures to counter partiality. Finally, such a community is characterized by an *organized skepticism*: No ideas are exempt from critical scrutiny.

A more recent list emerges from the work of the philosopher Helen Longino who discusses the characteristics of what she calls *ideal epistemic communities*. Such communities, she argues, will not merely tolerate, but actively encourage, dissent. They will have forums for the assessment of claims and the criticism of evidence. They will have publicly recognized standards by which claims can be assessed. Finally, they will exhibit an equality of intellectual authority, in the sense that any qualified member of the community is entitled to contribute to the debate.

Criteria of this kind take us part of the way, but their scope is too broad. They do not help us to identify those practices we customarily describe as *scientific*. An ideal community of historical inquiry, for instance, would also have these features, yet we may not wish to regard it as scientific. (The English term *science* has a narrower scope than,

say, the German *Wissenschaft*, but it is this narrower use of the term in which we are interested here.) So some further criteria are needed. Since the success of the natural sciences in modern times owes much to their use of measurement, mathematical modeling, and experimentation, we might want to add these characteristics as well. Practices would count as scientific to the extent they not only meet the standards of an ideal epistemic community but also engage in mathematical modeling, measurement, and experiment.

Such conditions would appear to be jointly sufficient for calling something a science: a cognitive practice that had all of them would count as scientific. But they are not individually necessary conditions: A practice does not need to have them all to count as a science. Archaeology, for instance, could count as a science even if it does not employ experiment. (Many archaeologists today do engage in laboratory work, but there was a time when they did not.) A multifactorial account abandons the idea that we can find a set of *both* individually necessary *and* jointly sufficient conditions for identifying a science. It regards science as a *family resemblance* or *cluster* concept. The practices we regard as sciences can be loosely clustered by way of what Massimo Pugliucci calls *threads*: features that are common to two or more instances, although there may be no thread that links them all.

Practices on the Spectrum

The previous paragraph spoke of archaeology "counting as a science." But this phrase could be misleading to the extent that it suggests the existence of clearly defined categories. A multifactorial approach makes *scientificity* (to use an ugly term) a matter of degree rather than kind. On this view, our cognitive practices can be placed on a spectrum. At one end will be clearly nonscientific practices (such as journalism) and at the other end will be those that are undeniably scientific (such as particle physics). In between we will find practices such as historical writing, legal reasoning, *soft* sciences (such as sociology), and quasi- or proto-sciences (such as string theory).

The question then becomes: At what point on the spectrum do we draw a line and declare that a practice purporting to be a science is not? On a multifactorial view, there can be no single answer

to this question. (This is one of the reasons Laudan gives for rejecting the use of the category.) But this does not mean the term *pseudoscience* has no use at all.

There does exist one necessary condition for calling something a pseudoscience. It is that the practice in question must present itself as a science. Journalism is not a pseudoscience simply because it lacks many of the features of scientific practice, for journalists do not claim that their practice is a science. To call a practice a pseudoscience is a way of drawing attention to the lack of substance in a particular practice's claims to precision and reliability. The use of the term *pseudoscience* will always be a move in an argument, to be deployed in a particular context to indicate the hollowness of a practice's claims. But this does not mean that the application of the term is arbitrary: There will be features of the practice in question that warrant this appellation.

Nonscience, Bad Science, Science Fraud

The distinction between science and pseudoscience is related to, but not identical with, a number of other distinctions. A first is between science and nonscience. Science is a particularly reliable form of cognitive practice, insofar as its use of measurement and mathematics allows for precise predictions. But as we have already seen, there can be cognitive practices that are reliable sources of knowledge that do not use such methods and which would, therefore, not count as scientific. To declare, for instance that the writing of history is not a science is not to denigrate the practice of history; it is merely to note that it employs different methods. It employs, for instance, narrative explanations rather than theoretical ones, and backs up those explanations with documentary evidence rather than experiments. It is only when proponents of a practice lacking scientific credentials claim that their practice is scientific that the term *pseudoscience* may be applicable.

Pseudoscience is also to be distinguished from both bad science and science fraud. Both categories are most helpfully regarded as applicable to the activities of individuals rather than to the collective activities (the social practices) in which they are engaged. Bad science can involve factors

such as poor experimental design or faulty statistical analysis. Instances of bad science can be found within practices that are scientific, practices whose norms include sound experimental design and reliable statistical analysis. The problem with (merely) bad science is not a structural problem with the practice in which it occurs. It lies in the failure of individuals to follow the procedures that practice encourages. The idea of fraudulent science adds to this the idea of an intention to deceive. So like *bad science*, the label *fraudulent science* is most appropriately applied to the behavior of individual scientists. The term *pseudoscience*, by way of contrast, is not applicable (at least in the first instance) to the activities of individuals. It is a way of describing the falsity of the pretensions of a cognitive practice.

The Limits of the Concept

The idea of a pseudoscience remains an *essentially contested concept*, and the present entry has done no more than offer one way in which it has recently been defended. Critics will continue to insist that there is something unsatisfactory about so vague a demarcation criterion: one that ranks practices along a spectrum and chooses to describe those toward one end as *pseudoscientific* when it seems useful to do so. But it is sometimes useful to do so. The term *science* has not merely a descriptive role; it also functions as an honorific. It is used of practices to which we extend a presumption of reliability, whose results we are inclined to accept even when we cannot check them ourselves. So when a practice takes on the mantle of science, it is claiming for itself a certain authority. We need to know if a practice claiming to be a science has the features that would entitle it to this kind of respect.

What follows if it does not? On the view defended here, relatively little. If we admit that there are reliable cognitive practices that are not scientific, then it does not follow from the mere fact that a practice is pseudoscientific that it is unreliable. We can be rightly suspicious of practitioners who protest too loudly that theirs is a science. They may be trying to cover up weaknesses in the practice in question. But the existence of such weaknesses is not essential to the idea of a pseudoscience, as defined here. All that follows

from the application of the term *pseudoscience* is that a practice lacks the particular kind of reliability we have come to associate with modern science. That is a modest claim, but one sometimes worth making.

PUNCTUATED EQUILIBRIUM

Punctuated equilibrium is the theory that one of the dominant modes of evolutionary change involves large, rapid changes in the morphology of a lineage, followed by evolutionarily long-term morphological stasis. It was introduced in 1972 to demonstrate the importance of theorizing in paleontology, as well as to broaden our understanding of the evolutionary process. This entry describes the historical foundations of this effort, its effects on the discipline of paleontology, and its broader significance for the study of evolution.

The Theoretical Significance of the Fossil Record

By the 1940s, paleontologists had arrived at a crossroad. On the one hand, their discipline had become increasingly involved in the petroleum industry, aiding in the search for oil. On the other hand, paleontology had been sidelined in the development of evolutionary theory as the powerful theory of Mendelian genetics merged with the even more powerful theory of Darwinian evolution, resulting in what is known today as the neo-Darwinian *Modern Synthesis*. As paleontologists stared out from this crossroad, it looked as if their future as an autonomous scientific discipline was in jeopardy. The developing theory of neo-Darwinian evolution seemed not to have any particular need for whatever information fossils could provide, and greater involvement with the petroleum industry would only steer them further away from biological science.

Paleontology's skies partially cleared in 1944, with the publication of George Gaylord Simpson's *Tempo and Mode in Evolution*. Of the many distinctive contributions of the book, Simpson's most important, lasting achievement was to show that patterns of long-term evolutionary change in the fossil record accorded with biologists' newly achieved understanding of how the composition of a population changes adaptively in response to environmental pressure. Simpson argued that the importance of this match between macro- and microevolutionary patterns lay not in the fact that it provided further evidence that Darwinian theory was correct. Rather, what was really significant about it was that it showed that the fossil record was a repository of genuine evolutionary patterns, perhaps only *some* of which reflected the influence of Darwinian mechanisms. A fully mature evolutionary theory, he argued, would have to be able to account for all patterns in the fossil record patterns, *whether or not* they confirmed expectations that were specifically Darwinian.

Simpson's insight was a lifeline to paleontology as it struggled to find its way forward, for it outlined a distinctive role for the study of fossil patterns in the future development of evolutionary theory. The theory of evolution could not be considered complete so long as the fossil record remained unaccounted for. Since paleontologists alone were competent to study it, there was an opportunity for them to contribute something to evolutionary theory which fell exclusively under the purview of their discipline. Indeed, Simpson himself had described an apparently non-Darwinian evolutionary mechanism in *Tempo and Mode*, which he called *quantum evolution*, in which large leaps across morphospace seem to occur over a timescale that made little sense from a traditional Darwinian perspective. Despite the promise that it held for paleontology's disciplinary ambitions, Simpson would eschew its non-Darwinian status in subsequent work, attributing it instead to allopatric speciation, which was by then part of the neo-Darwinian orthodoxy.

That transformative potential was not lost on Stephen Jay Gould, who, from his first days as a Columbia graduate student in 1965, saw that the survival of paleontology as an autonomous science rested solely on its ability to make contributions to evolutionary theory that could only be

derived from fossil patterns. Gould would develop Simpson's perspective on the evolutionary significance of the fossil record into lifelong fixation on the need for paleontology to articulate laws of nature that governed large-scale evolutionary change and which therefore formed an essential component of a complete theory of evolution. Gould's preferred vehicle for that fixation would be the theory of *punctuated equilibrium*.

Origins of the Theory of Punctuated Equilibrium

Interestingly, the theory of punctuated equilibrium began not with Gould but with another Columbia graduate student, Niles Eldredge. In 1971, Eldredge published a paper that would help make theorizing a permanent fixture in paleontology. This paper made two significant observations. The first was that the received view on how speciation occurs—the allopatric model—was not obviously consistent with the dominant mode of evolutionary change, in which lineages gradually transform through adaptation to their environments. Allopatric speciation, by contrast, involves relatively rapid morphological divergence in which genetic drift is assumed to play a central role. Second, Eldredge described the curious tendency of a certain trilobite lineage to undergo geologically rapid change (consistent with allopatry) but then persist essentially unchanged for millions of years, a feature that he attributed to stabilizing selection.

Gould seems to have seen in this work a singular opportunity to challenge the neo-Darwinian orthodoxy. The year before Eldredge's paper was published, Gould had been invited to present a paper on theoretical models of speciation and their role in paleontology. Not knowing much about the topic himself, Gould asked Eldredge to join him as a coauthor. The resulting paper, "Punctuated equilibria: An alternative to phyletic gradualism," reiterated Eldredge's emphases on both the illness of fit between the allopatric model and the received view on evolutionary change, and on the surprising long-term stability of several fossil lineages. Whereas Eldredge's original paper had attributed this stasis to stabilizing selection, however, Eldredge and Gould's (1972) "Punctuated equilibria" would make the

unorthodox claim that stasis was a consequence of allopatric speciation.

This seemingly minor change in view held important implications for paleontology's ability to make a distinctive contribution to evolutionary theory. Paleontology could not claim that allopatric speciation has a phenomenon uniquely disclosed by the fossil record. Nor would its theoretical ambitions be facilitated by the embrace of stabilizing selection as an explanation for stasis, since such an explanation would have been consistent with the generally Darwinian understanding of evolution. However, by linking stasis in the fossil record to the non-Darwinian nature of allopatric speciation and treating them as two stages of a single causal process—the *punctuated* morphological change symptomatic of allopatry, which causally gave way to an *equilibrium* stage lasting millions of years—paleontology could assert exclusive access to a fossil pattern not predicted by Darwinian theory.

The Transformative Role of the Theory of Punctuated Equilibrium

In this way, the theory of punctuated equilibrium was developed more out of paleontology's need for an original theoretical framework that could distinguish it from Darwinian microevolutionary theory than from a pressing need to solve an evolutionary puzzle. Neither allopatric speciation nor morphological stasis was considered to be a puzzle in 1972. Eldredge and Gould reinterpreted the fossil record (as well as the allopatric model of speciation) in order to manufacture a theoretical puzzle that only paleontologists could solve. Viewed from this perspective, the theory of punctuated equilibrium did not succeed in providing the "alternative to phyletic gradualism" that would have helped to clear some space for paleontology in the ecology of evolutionary disciplines. Orthodox Darwinian critics of the theory claimed that both *punctuation* and *equilibrium* could be understood using traditional and more conservative population genetic theory, criticisms that Eldredge and Gould would eventually accept. The received view is that what appears to be stasis in the fossil record is in reality the failure of the many short-lived instances of evolutionary change to leave fossil traces, and that the reason morphological changes appear to occur

primarily during speciation events is because speciation is the only kind of evolutionary change that really sticks.

Looking at the theory of punctuated equilibrium in a broader historical and disciplinary context, however, it made an undeniably lasting impression on evolutionary thinking and on the fortunes of paleontology in particular. For Eldredge and Gould had compelled the community of evolutionary biologists to finally heed the warning that had been issued by Simpson a generation earlier: A complete understanding of the evolutionary process cannot be derived from studying changes in gene frequencies over short periods of time. There are evolutionary phenomena that can only be observed on the longer timescales represented in the fossil record. Stasis is one of them. That it turns out to have a perfectly serviceable Darwinian explanation is immaterial to the fact that, had it not been for paleontology, we would not have known that the evolutionary process is compatible with millions of years of morphological stability.

The acknowledgment of *stasis as data* and of paleontology's necessary role in alerting us to it, combined with Gould's consistent and high-profile advocacy for the theory of punctuated equilibrium, form a major part of the explanation for why paleontology would grow into an increasingly theoretical discipline after the early 1970s. After that point, it could no longer be maintained that paleontology was merely a form of biological stamp collecting. Paleontologists were disclosing new evolutionary phenomena and were developing novel explanatory theories to account for them, some of which were significant departures from traditional Darwinian thinking.

Gould was involved in several independent efforts to advance the disciplinary status of paleontology; each of them focused on making a specifically paleontological contribution to our understanding of the nature of evolutionary change. Although none of his specific proposals ever enjoyed widespread uptake, he understood perhaps better than any other member of his generation that the future of the discipline hung in the balance, and that its very survival as a science would be determined by the extent to which evolutionary theorizing could be elevated to a central component of paleontological practice. His efforts

to introduce a culture of theorizing into paleontology (in which he was joined early on by others such as David Raup and Thomas Schopf) were successful not only in transforming the discipline but also in helping to recapture the essential breadth of evolutionary theorizing that Darwin himself had exhibited in the *Origin*.

R

RATIONAL MECHANICS

This locution was introduced by Sir Isaac Newton in the Preface to his *Philosophiae Naturalis Principia Mathematica* (*Mathematical Principles of Natural Philosophy*):

The ancients divided mechanics into two parts: the rational, which proceeds rigorously through demonstrations, and the practical. [. . .] In this sense, rational mechanics will be the science, expressed in exact propositions and demonstrations, of the motions that result from any forces whatever and of the forces that are required for any motions whatever. (1867, p. xiv; first English translation 1729)

Newton argued that rational mechanics is a branch of mathematics and went as far as to state that geometry is part of mechanics. Modern scientists are likely to disagree with Newton on this second point; to them, mathematized mechanics is geometry plus motion, time, mass, and force.

The new terminology was widely accepted on the Continent but was less common in Great Britain, perhaps because of the British distrust, in the period 1750 to 1820, of highly theoretical studies. By the 1950s, in English-speaking countries, the elegant and precise expression *rational mechanics* was considered archaic. It was supplanted by *theoretical mechanics*, which excludes rational theories of materials, and *classical mechanics*, which is too generic. The following sections trace

the history of rational mechanics from its origins in classical Greece to the contributions of Renaissance thinkers such as Galileo, Huygens, and Descartes and continuing with Newton and Enlightenment figures such as Euler, Bernoulli, D'Alembert, and Lagrange, and the work of their successors in the 19th and 20th centuries. The entry continues with an account of the theoretical framework built on the foundation of Newton's achievement, followed by a description of subsequent efforts to axiomatize the concepts underlying the fundamental principles of rational mechanics. The entry concludes with an explanation of the mechanist philosophies and models of the universe that held sway until the early 20th century, when the advent of thermodynamics, electromagnetism, and the theories of relativity and quantum physics would challenge the basis of the mechanical view of the world.

History

As Newton said, the substance of the theory goes back to the ancient Greece. In the 3rd century B.C.E., Archimedes had already rigorously formalized the law of the lever and the principles of hydrostatics in works that survive today. For two millennia, Archimedean mechanics set exacting standards of excellence.

By the early 17th century, scientists were ready to take up the challenge. In 1638, Galileo Galilei published a short Latin treatise entitled *De Motu* (*On Motion*), in which he established in purely Euclidean fashion the laws of uniform and

uniformly accelerated motion. His pupil Evangelista Torricelli gave a better formulation of this question in his *On the Motion of Heavy Bodies* (1644). That very same year, René Descartes gave a precise set of (wrong) rules for impact. This early period of discovery reached a pinnacle with the publication of Christiaan Huygens's *The Pendulum Clock: Or Geometrical Demonstrations Concerning the Motion of Pendula* (1673), today mainly cited for the theorems on pendular motion and centrifugal forces, which became the model for all subsequent rational enquiries into natural philosophy.

The publication in 1687 of Newton's *Principles* raised mechanics from infancy to adulthood. Modern readers expecting a textbook on dynamics will be dismayed; this is a product of Baroque times, to be savored like the music of Bach. After two introductory sections on *Definitions* (i.e., space, time, and motion) and the *Axioms of motion* (the three Newtonian laws of dynamics), the treatise is divided into three books: The first discusses the motion of a point attracted to one or two fixed centers by central forces; the second derives approximate formulas for bodies moving in a resisting fluid; the third contains the law of gravitation, from the first principles to the irregularities of moon motion.

The *Principles* is a concise and intensely mathematical work, and rare is the reader, then or now, who can master its content in a lifetime. It took the world a generation or two to catch up with Newton's ideas. Then, a handful of brilliant mathematicians, all born on the Continent at the beginning of the 18th century, who as youths had absorbed Newton's and Gottfried Wilhelm Leibniz's writings, were able to create new theories, expressed in terms of Leibnizian calculus, out of the Newtonian foundations.

It all happened in less than 30 years. In 1736, Leonhard Euler published the two-volume treatise *Mechanics, Or the Science of Motion, Analytically Expounded*, where the dynamics of a single particle appears as a branch of three-dimensional analytic geometry. His friend Daniel Bernoulli, in the *Hydrodynamics* (1738), transformed hydraulic engineering into a scientific theory based on what we would now call the conservation of mechanical energy (Bernoulli's theorem). In 1743, the mathematician and philosopher Jean D'Alembert, today

mainly famous as an exponent of the Enlightenment, reduced dynamics to statics by considering the equilibrium of those components of the applied forces which are destroyed by the constraints (D'Alembert's principle). Alexis Clairaut, in his *Theory of The Figure of the Earth* (1743), reduced fluid statics to a few equations.

The most remarkable exponent of this group is undoubtedly Euler. In a series of brilliant papers published from the 1740s onward, he single-handedly created fluid dynamics, linear elasticity, and the theory of rigid bodies in a form not very different from that encountered in our textbooks. By forging the field viewpoint in mechanics, Euler shaped the development of mathematical physics for the next two centuries.

An approach to rational mechanics different from Euler's was initiated by the Italian-French mathematician Joseph-Louis Lagrange. His *Analytical Mechanics* (1788) was an attempt to base all of mechanics on the general laws of statics, supplemented by the principle that reversed accelerations are forces per unit mass. Lagrangian mechanics is completely analytic, without any trace of geometry or physical intuition. It is one of the best examples of an uncompromising attempt at a rigorous foundational program in science.

By about 1820, most of the elementary theory had already been established and expounded in textbooks. At the same time, higher research advanced at a rapid pace. The engineer-mathematician H. Navier gave the general equations of linear elasticity (1821). Augustin-Louis Cauchy discovered the stress tensor, which expresses the properties of the surface forces in a material continuum (1829). William Rowan Hamilton, starting from Lagrangian mechanics, created a new form of the equations of motion of a system of particles, one which unveils a fascinating dualism between dynamics and geometrical optics (1834). Gaspard-Gustave Coriolis discovered the equations of relative motion (1835).

In the 20th century, with the arrival of elementary particles and the theories of relativity and quantum physics, classical mechanics was exiled from the mainstream of science. Yet, unbeknownst to physicists, the theory continued to grow. Prominent among the new developments was, after the Second World War, an impressive expansion of continuum mechanics, mostly under the energetic

leadership of Ronald Rivlin in Great Britain and Clifford Ambrose Truesdell III in the United States. Besides discovering a host of new results, Truesdell and his students formalized *rational continuum mechanics*, setting it firmly in the old tradition.

Theory

The general framework of rational mechanics was artistically polished in all its myriad detail during the 19th century. As a result of this activity, not much has changed in the exposition of its foundations since the appearance of a number of influential treatises in the early decades of the 20th century. What follows is a schematic summary of the key concepts.

First comes *statics*, the theory of equilibrium, and *kinematics*, the description of motion, then *dynamics*, the study of forces and motion. While kinematics is essentially the Euclidean geometry of moving bodies, statics involves two new physical entities: mass and force. *Mass* is the quantity of matter in an object and is measured by its inertia, that is, its resistance to a change of velocity. *Force* is a measure of the interactions between objects or between objects and fields. The product of mass and velocity is the *momentum* of a moving object, which is a measure of its quantity of motion. Force, velocity, and momentum are vectors.

The fundamental laws of dynamics are Newton's three laws of motion. Despite the strength of Newton's polished style, they are best understood in a slightly modernized form.

Lex I: In the absence of forces, a particle moves with constant velocity.

Lex II: The rate of change of the momentum of a particle is equal to the impressed force.

Lex III: For every force from Particle A on Particle B, there is an equal and opposite force from B to A.

These axioms apply to mass points; in other words, particles or geometrical points endowed with mass and motion.

The first law defines a class of reference frames, the inertial frames. Any two inertial frames move relative to one another with uniform velocity. Newton's laws only apply to motions relative to an inertial reference frame. The first law also defines Newtonian time.

When describing systems of particles, three additional quantities become important. The total kinetic energy is half the sum of the products of masses and their squared velocities. The work done by a force is the product of the magnitude of the force and the distance moved in the direction of the force. The *moment* of a vector (e.g., force or momentum) is the cross-product of the position vector with that vector. In systems, we must also distinguish between *internal* forces, acting between any two particles in the system, and *external* forces, exerted by agents outside of the system.

These definitions being provided, we obtain from Newton's laws three general principles which apply to all systems of particles. The *principle of momentum* establishes that the rate of change of the total momentum is equal to the sum of the external forces. According to the *principle of moment of momentum*, the rate of change of the total moment of momentum about any fixed origin is equal to the sum of the moments of the external forces about that origin. Finally, the *work-energy principle* states that, in any displacement of a body, the change in the kinetic energy is equal to the work done by all forces, internal and external.

From these principles, the *conservation laws* are immediately obtained. If the sum of the external forces is zero, then the momentum is conserved; similarly, if the sum of the moments of the external forces is zero, then the moment of momentum is conserved. When the forces are derived from a potential function, then mechanical energy is conserved too.

Next comes the theory of *rigid bodies*. The kinematics of rigid bodies is the purely geometrical theory of groups of isometric motions in space. Combining these kinematic results with the principle of moment of momentum yields Euler's equations, which express the properties of rotary inertia and explain the counterintuitive behavior of massive, swiftly rotating objects.

Besides this central core, rational mechanics has many subdisciplines. Among the most prominent ones, in no particular order, are analytical mechanics, statistical mechanics, celestial mechanics, general continuum mechanics, elasticity, fluid mechanics, and acoustics. Each of them has its own set of rules and is partially independent of the others. Unfortunately, even a cursory survey of

their characteristics would far exceed the scope of this article.

Axiomatics

After the appearance of Newton's *Principles*, the further development of rational mechanics raised a number of foundational problems. The evidence for or against the existence of absolute space and time, the physical meaning of inertia, the equality of inertial and gravitational mass, the logical status of the concept of force, and the degree of generality of the different principles of mechanics worried scientists for nearly two centuries. Although the relevance of these problems has greatly diminished since the advent of modern physics, a tinge of insecurity still encircles the edge of pedagogical presentations.

One way to overcome this situation would be to produce an axiomatization of those principles which intuitively hold for classical space, time, matter, and motion. This would amount to solving the heart of the Sixth Hilbert Problem, proposed by David Hilbert in 1900. Hilbert asked for an axiomatization of mathematical physics, starting from mechanics.

There have been three main attempts at a solution of this part of the Sixth Hilbert Problem, greatly differing in aims and methods. In 1908, the mathematician Georg Hamel, a student of Hilbert, taking inspiration from Hilbert's axiomatization of Euclidean geometry, introduced groups of postulates for the mechanics of extended bodies. About 50 years later, in a different scientific climate, the logicians John C. C. McKinsey, A. C. Sugar, and Patrick Suppes strove for a Bourbakist approach to point mechanics. Somewhat later the engineer-turned-mathematician Walter Noll sought instead for a conceptual framework general enough to include the then new theories of continua. Variations on these themes have been put forward over the years. Regrettably, as late as the second decade of the 21st century, there is no general agreement as to the respective merits of these competing views.

Mechanicism

It is only natural to think of the world as a complex machine. This doctrine, called *mechanicism*,

was an essential feature of the Scientific Revolution. It was originally sparked by the rediscovery of the ancient atomism during the Renaissance and continued to develop over the centuries. Although far from providing a correct interpretation of the universe, its different incarnations gave direction to the research of physicists.

A full-blown mechanistic model of the world was developed by René Descartes in 1644. According to Descartes, the cosmos is filled with matter. The essence of matter is extension. Vortices and currents of matter are the causes of gravity. Animals are pure machines. An external God is the ultimate mover of these fluxes of matter.

Descartes's dynamical universe broke completely with the Aristotelian tradition and marked most of the development of physics up to the 1720s. It gave us the principle of inertia, the conservation of momentum, a theory of light, and an explanation of planetary motion but was not grounded on experiments and could not predict new phenomena. In the end, it was denounced as fiction by intellectuals as diverse as Huygens and Voltaire. After an academic struggle that lasted for decades, around 1740, Descartes's philosophy was superseded by Newtonian science.

Newton's mechanicism owed nothing to Descartes's vortices. It was essentially a theory of forces, grasped by experiments and described through mathematics. This abstract structure is an attribute of an otherwise incomprehensible God. Newton also believed in the existence of atoms and of "a very subtle spirit pervading gross bodies and lying hidden in them," but since he could not prove his ideas with facts, he did not elaborate further.

Several mechanistic theories of nature arose during the 19th century. Between 1800 and 1830, Pierre-Simon Laplace, Siméon Denis Poisson, and Claude-Louis Navier attempted to establish a new science, called *mécanique physique*, which aimed at explaining capillarity, elasticity, and fluid dynamics by considering hypothetical intermolecular forces. Another unified theory of the world was *energetism*, especially advocated by the chemical physicist Wilhelm Ostwald in the 1890s, which purported to derive all of physics from the principle of conservation of energy. Also of importance were the various mechanical models of the *luminiferous ether* propounded by British

physicists from the 1860s onward. Clearly, every one of these philosophies contained a grain of truth but was far from being entirely correct.

Mechanicist philosophies reached an end in the late 19th century, with the advent of the new sciences of thermodynamics and electromagnetism. In his influential book *The Science of Mechanics* (1883), Ernst Mach remarked that the older knowledge is not necessarily the foundation of more recent theories. A few years later, Albert Einstein's special theory of relativity (1905) gave the death blow to all attempts at purely mechanical explanations of the world.

RATIONALITY

There are numerous models of *rationality*, the term often used interchangeably with *reason* to describe logical mental operations of human beings. The notion of rationality is at the core of epistemology and formal logic. Throughout this essay, *rationality* is an umbrella term to describe various types and functions of focused human intellectual activity as well as the instrumental use of thought and thought processes to carry out epistemological endeavors and achieve pragmatic goals. As generally conceived of in the Western tradition, especially since the 17th century, human rationality works by means of cerebral operations in, upon, and through the natural, material world of existence as a function of the human capacity to reason. Consciousness and self-consciousness, perception and logic, ideas and information, thoughts and thinking, and similar immaterial actualities are seen as by-products of particular areas of the physical brain in communion with faculties of the mind. In this essentially Western worldview, *knowledge* has been understood to be rooted primarily in processes of rationality, rather than in emotion, intuition, or the *received knowledge* of tradition or religion. Contemporary philosophy and epistemology, however, are paying much attention to the latter categories—how to understand them as kinds of knowledge and bringing them conceptually under the umbrella of what is described here as rationality.

Recent developments in epistemology, psychology, neuroscience, and computer science have spurred further interest in resolving the *mind-body* conundrum that is the offspring of René Descartes' *cogito ergo sum* (I think, therefore I am). Neuroscientists, psychologists, social scientists, and philosophers increasingly focus on the systematicity of thought and cognitive domains. *Mind-brain identity theory* and similar models emerge from these disciplines, all of which attempt to decipher connections among mental states and processes and interactions of the physical brain with the material world. Theories of rationality are often divided into two broad categories: *normative* or *theoretical* (what rationality is or might be) and *descriptive* or *practical* (what rationality does or should do). Similarly to the exposition of

rationality theories, theories of consciousness and representation continue to evolve in great depth and detail; owing to limitations of space, however, that discussion is not included in this overview.

Theories of rationality—and by extension, dicta as to who and what is *rational*—are instrumental in fields of politics and government, law, economics, political science, sociology, and cognitive psychology. The intensity of the centuries-long debate over rationality, its characteristics, and its proper application is precipitated at least in part by the close relationship between claims to rationality and claims to authority and power. The following discussion provides a historical overview of approaches to the question of rationality, describes some theoretical positions which result, and presents several frameworks for contemporary investigation. Whereas the primary focus is on the relationship of consciousness, reason, and selfhood from a Western perspective, especially since 17th- and 18th-century Age of Enlightenment, it must be noted that development of the role of reason in Eastern traditions is pertinent but not developed, given space constraints.

Understanding Rationality

There is no single theory of rationality, and over the thousands of years humans have reasoned about the nature of the mind, thought, and cognition, a massive body of philosophical, scientific, metaphysical, and psychological models have been generated. Mario Bunge, noted philosopher-scientist and author of the eight-volume *Treatise on Philosophy*, finds that the lack of consensus as to what rationality is and what it can be expected to accomplish is due to the fact that the word describes at least seven different concepts.

These are as follows:

1. Conceptual (aiming for precision and measurability),
2. Logical (aiming for consistency),
3. Methodological (working to question, prove and justify),
4. Epistemological (providing empirical, factual support that is consistent with other facts),
5. Ontological (providing a worldview consistent with existing knowledge),
6. Valuational (aiming for goals that both could and should be attained), and
7. Practical (being instrumental in attaining those goals).

Any one of these definitions or conceptual frames taken in isolation from the others only partially describes rationality, with the consequence that applications based upon those understandings are what Burge labels as only *pseudorational*.

Through the 20th century, essentially metaphysical and supernatural phenomena have often been excluded in consideration of what is strictly *rational*, relegated to realms of speculation and imagination that include mysticism, religion, ethics, superstition, intuition, and similar states of mind. However, as will be seen, recent work in neuroscience, computer science, critical theory, and similar disciplines are blurring those boundaries to some extent.

Rationality Before the Common Era

Philosophers have long declared that human beings are inherently rational. Aristotle, in the 4th century B.C.E., defined human beings as the *thinking animal*, and in 1660, Blaise Pascal called humans *thinking reeds*. Even so, in prehistory and to some extent in classical Greek philosophy, the universe itself was the source of all intelligence—observing, controlling, and acting through the material world, including human beings. Decision-making was the corollary of divination. Humans searched in bones, entrails, smoke, and dreams for signs and portents and sought direction through magical divination or instruction passed from the First Cause or unmoved Mover through prophets, priests and priestesses, and oracles.

Evidence of human rationality greatly predates theorizing about it, with written evidence beginning around 3500 B.C.E. The inquiry into the nature, scope, and acquisition of knowledge became a distinct philosophical genre, *epistemology*, also dealing with related concepts such as perception, memory, belief, and justification. Thales of Miletus (c. 620 B.C.E.–546 B.C.E.), often referred to as the first philosopher, believed that the earth floats on water and that “all things are full of God,” and is

credited as being the first to assert that the human soul is immortal.

Pythagoras (c. 570 B.C.E.–c. 495 B.C.E.) saw the natural world as being ordered according to a set of mathematical ratios. He promoted a way of life that included a strict moral code, which included the mandate to train the memory, and his teachings influenced both Plato and Aristotle. Heraclitus (535 B.C.E.–475 B.C.E.) postulated universal *logos* (pure rationality), which humans could tap into but which most chose to ignore and to continue as sleepwalkers. Epicurus (341 B.C.E.–270 B.C.E.) questioned the usefulness of formal logic and developed a hedonistic approach to life that involved the use of reason primarily to avoid fear. Plotinus (204 C.E.–270 C.E.) was a Neoplatonist who believed that the human mind was primarily rooted in the material world but was nevertheless capable of experiencing *the One*.

Even now, there is a question as to whether rationality can be taught and, if so, how would such progress in critical thinking be effected and measured. Two paramount philosopher-teachers of rationality were Socrates (c. 470 B.C.E.–c. 399 B.C.E.) and his disciple Plato (c. 428 B.C.E.–c. 347 B.C.E.), who presented Socrates' ideas in the form of *Socratic dialogues*. Two key elements of Socrates' philosophy of rationality presented in Plato's dialogues are the *Theory of Forms* and the *Allegory of the Cave*. For Plato, knowledge or truth separate from simple opinion or belief exist but is predicated upon absolute, unchanging pre-existing Forms. What we glean from our experience, thought, and reflection has been called into material being as reflections of those ideal realities. Since the eternal Forms are antecedent, then our immortal souls had full knowledge of them but *forgot* that absolute ideal world at birth. Thus, *learning* is a process of simply remembering.

Plato's *Allegory of the Cave* is a metaphor for existence as a state of coming to know what the soul already knew. Here, Plato describes humans as prisoners chained in a cave facing a wall of shadows which they believe to be reality. They don't understand that the shadows they see are mere reflections of real things being moved around behind the prisoners outside of their field of vision but in front of a fire that is casting the shadows.

The prisoners can break free (i.e., the mind can escape the Cave) only by coming to understand the Forms which constitute true reality that prevails outside the Cave in sunlight.

Like Plato and Socrates, Aristotle (384 B.C.E.–322 B.C.E.) believed that the greatest attainment of human life was possible only in attempting to acquire knowledge through reason or *logos*. According to Aristotle, all of natural creation is arranged in hierarchically ordered taxonomy or "Great Chain of Being," with humans at the crown based upon our complex intellectual abilities. He explains the relationship of body and soul (*psyche*) with the analogy that if the eye were an animal, sight would be its soul. Reason, or *nous*, is the highest form of rationality; the *unmoved Mover* of creation is divine *nous*. Aristotle conceived of two forms of human knowledge, *sophia* or wisdom and *phronesis* or practical knowledge; these correspond generally to conceptions of theoretical and instrumental rationality. In stating that *every primary substance falls under a secondary substance*, Aristotelian logic foreshadowed today's concepts of epistemological *supervenience* (discussed subsequently).

Concurrent with the emergence of Western epistemological models of human reason, a set of teachings that may be termed *dharmic philosophies* developed in Asian cultures. These, central to Buddhism, Jainism, and Hinduism, advocate practices (such as meditation) that develop *mindfulness* as in Buddhism and, with the spread of these teachings to China, encourage efforts to manifest Confucian *reasonableness* as opposed to logical rationality. In the 6th century B.C.E., the Chinese sage Laozi (in the older, Wade-Giles transliteration, Lao-tzu) taught his followers to conform to events in their lives through non-willful action, passively but consciously following the Way (the Dao).

Western Early Modern Philosophers on Rationality

Francis Bacon (1561–1626), English statesman, scientist, and philosopher, emphasized *inductive reasoning* (building a body of knowledge through empirical sense experience in the natural world),

furthering development of the scientific method as well as establishing the method of inductive logic. He said *Knowledge and human power are synonymous* and believed humans had two souls, one animal and one rational. Bacon viewed the intellect to be both lazy and restless by nature, subject to committing errors in reasoning under the influence of four types of mental *idols*: idols of the tribe, the marketplace, the cave, and the theater. Bacon strongly influenced such eminent philosophers as John Locke, David Hume, John Stuart Mill (1806–1873), and Bertrand Russell (1872–1970).

René Descartes (1596–1650), the *father of modern philosophy*, established the school of thought now known as *rationalism*, postulating that the ultimate source of knowledge is reason. This was a move away from faith in classical authorities and toward reliance upon the individual's powers of reason, especially deduction. He believed some truths exist a priori and can be known innately through the power of reasoning, verified through sense knowledge, experience, and experimentation.

In *Discourse on Method*, Descartes describes a formula to arrive at these conclusions using four rules. The first was “never to accept anything as true that [he] did not know evidently to be so.” The second was to take a mathematical approach and divide that which he was examining “into as many parts as possible,” dealing with each individually. The third was to order his thoughts from the simplest and easiest to know gradually to the more complex. And the last was to make “enumerations so complete and reviews so general that [he] would be sure of having omitted nothing.” After rigorously employing this method for several months and discarding everything he could not strictly confirm and verify, Descartes was left with one truth “so firm and so certain” that he could not shake it: *Cogito, ergo sum* (“I think, therefore I am”).

In the centuries since Descartes arrived at his core truth, other philosophers have concluded that the *ergo* clause does not necessarily follow the *cogito*—that thinking does not necessarily prove *being*. Even so, Descartes' method of *radical doubt* and its division of all that is into the categories *res logicans* (things thought) and *res extensa* (everything else) established the humanistic

approach to rational explanations of reality that undergirds the modern Western tradition.

Historian and political philosopher Thomas Hobbes (1588–1679) was Descartes' contemporary, both conferring with and critiquing him. Hobbes termed his theories of moral philosophy and of rationality as a form of computation. His interest in the workings of the mind through sensations and imaginings, especially as expressed in language, brought him to appreciate the importance of linguistic *signification*, or *naming*, to instrumental rationality. His conceptualization of the human as a *thinking body* was central to his theory of *materialism*; Hobbes did not believe that a thought could exist without a body to think it. His major work, *Leviathan*, elaborated his conception of a *social contract theory* which, similarly to the Greek *polis* of Aristotle, requires the cooperation of free, equal, and rational participants.

In writings opposing Hobbes's conservative philosophy, the politically idealistic John Locke established (British) *empiricism*. He asserted that all knowledge results solely from the individual's experience of the world apprehended through the senses; thus, he advocated experimental science as an appropriate use of reason. The mind, according to Locke, was “an empty cupboard,” a *tabula rasa* or blank slate, until the senses imprinted experience on it. Locke believed that some aspects of existence could be apprehended through reason, while others could not; his treatise *Essay on Human Understanding* addresses this dichotomy.

“Heretic extraordinaire” Baruch de Spinoza (1632–1677) developed a radical philosophy that included elements of Stoicism, Talmudic principles, and Cartesian duality. He was attacked and excommunicated from his Sephardic Jewish community for denying the existence of the soul or of an Old Testament deity (“a God existing only in the philosophical sense”) or of a body of received law or morality binding on humans. However, his theory of rationality—that passion and emotion should be overcome so that all things might be deduced by the rational mind from a few basic principles—could be considered more *pantheistic* than atheistic, in that he believed all material existence was imbued with and part of a God-force. He used foundational axioms and definitions to

differentiate between two forms of knowledge: *ratio* (rational) and *scientia intuitiva* (intuitive).

Scottish philosopher and historian David Hume (1711–1776) is noted for study of what has become known as *philosophical naturalism* and *moral rationalism*. He rejected Descartes' notion of a priori knowledge and believed that what we can know through the mind will only be known as a result of the impressions of the world processed through experiences. His work influenced scholars such as economist Adam Smith, biologist Charles Darwin, and Utilitarian philosopher Jeremy Bentham.

Gottfried Leibnitz (1646–1716) was a polymath and diplomat whose love of mathematics, especially geometry, eventually led him to develop novel systems of calculus. Subsequent to conversations with Spinoza in 1676, he turned his attention more fully to philosophy. Perhaps his most important contribution to philosophy of mind is his notion that preestablished harmony between mind and body is the basis of rationality. His reflections constitute a critique of both Cartesian dualism and of rationalism. By including consideration of human striving, motivation entered epistemological philosophy.

The German philosopher Immanuel Kant (1724–1804) is a central figure in philosophy generally and especially in consideration of the influence his *Critiques of Pure Reason* (the original leaning toward metaphysical idealism and the revision more toward realism) have had on thinkers who have followed him. He attempted to delineate the sources and conceptual categories of human knowledge and to elucidate a method for acquiring and applying it. Kant rejected theories asserting that experience was the necessary foundation for rational thought insofar as he saw certain categories such as theology, psychology, and cosmology as existing but being beyond the realm of human sense experience.

Georg Wilhelm Friedrich Hegel's (1770–1831) early studies focused on both philosophy and theology, with the result that the scope of his writings spans and integrates multiple domains. Using logic as a starting point, Hegel searched for a philosophical system which could attain *absolute knowledge* that would answer all questions—epistemological, ontological, and metaphysical. The Hegelian system conceives of all things,

including the human mind and its capacity for rationality, as embedded within pure, conscious, eternally active Spirit or *Geist*.

Postmodern Rationality

In the modern-to-postmodern paradigm shift in ways of thinking about thinking and what it means to be *rational*, previously established *givens* are increasingly contested. Although most would not disagree that humans have an innate ability to perceive situations, alternatives, and potential outcomes as well to ruminate upon a broad range of immaterial abstractions through cognition and reason, arriving at a common *truth* as a result of this philosophizing is no longer expected. The consensus currently is that attempting to delineate a set of universalized *norms* for rationality will not succeed, for a number of reasons. For example, there are disputes about how rationality should be defined, what rationality should do, and how rationality should be measured or judged based upon consensually defined norms. And with respect to the latter, philosopher James Broome reasons that *rationality* may not be *normative* at all. As a result, a variety of *isms* tied to rationality has developed, a few of which are described below.

Foundationalism

Proper or well-founded beliefs are necessary ingredients for effective reasoning. Some beliefs are *basic* and provide justification for further elaboration. Aristotle's *Posterior Analytics* and Descartes' *cogito* rest upon a foundationalist approach. Rationalism and empiricism are not at odds with this model. A philosophical debate as to the necessary interconnection of these basic beliefs was generated in the mid-20th century, metaphorically arguing, for example, whether a raft of beliefs or a web of beliefs would produce the most justifiable derivative (or secondary) beliefs.

Perspectivalism (or Perspectivism)

As enunciated generally by Friedrich Nietzsche and further developed by John Frame, Vern Poythress, and Jonathan Kvanvig, this model lies somewhere between *relativism* and *absolutism*. A corollary to *foundationalism*, it states that it is impossible for an individual to be objective, since

each person experiences the world from a unique subject position. Thus, many ways of seeing and reasoning exist, some more valid than others, but none is objectively true. Nietzsche (1844–1900) says, “Insofar as the word ‘knowledge’ has any meaning, the world is knowable; but it is interpretable otherwise, it has no meaning behind it, but countless meanings. . . . There are many sorts of eyes. The sphinx too has eyes; consequently, there are many sorts of ‘truths,’ and consequently there is no truth” (*Will to Power*, Section 540).

Coherentism

The *coherence theory of justification* (which differs from the *coherence theory of truth*) requires that various underlying beliefs arise out of a body of beliefs consistent with each other. This thesis is generally considered to be at odds with *foundationalism*, generating a variety of arguments for and against. Some consensus has developed around its relevance to moral epistemology based in part upon interpretations of the work of John Rawls (1921–2002).

Internalism and Externalism

One step in rationalization is to apprehend and justify certain beliefs. In epistemology, the debate framed as *internalism* versus *externalism* has to do with whether the individual can rightly justify a belief based upon mental content is accessible solely from within that person’s consciousness or whether it is necessary that the individual draw upon external sources. Externalists aver that information drawn from outside the interior psychological states of the knower is a necessary condition for knowledge. Both *internalist* and *externalist* models of belief justification include semantic, motivational, and historiographical theoretical subcategories.

Evidentialism

Related to rationality, evidentialism is a type of *supervenience theory*—that is, sets of properties are hierarchically ordered to determine which properties are requisite (which *supervene*), stating that a change in one set of properties will cause a change in related property sets. Evidentialism requires that a belief (or disbelief or withholding

of belief altogether) must be justified by *acceptable* evidence and *good reasons* which support the belief. The *evidentialist* would say that *One ought to believe only what one can believe*. However, this can trigger heated discussion of what constitutes valid evidence and which categories of evidence properly supervene upon other categories. Forms of this position can be seen, for example, in the writings of David Hume and Bertrand Russell.

The Rationality (and Irrationality) of Groups

In a shift from a focus on the rationality of individuals, scholars in the 19th and 20th centuries began developing theories of collective or group rationality. In some cases, though, what emerged were theories demonstrating groups often behave more irrationally than individuals acting alone would be likely to behave.

German philosopher-political economist Max Weber (1864–1920), taking a sociological viewpoint to investigate patterns and processes of *rationalization*, identified four types of rationality (practical, theoretical, substantive, and formal) conforming to his four modes of social action (affectual, traditional, value-rational, and means-end). He conceived of these as universal in some sense but developing in certain ways specific to Western cultures or *life-spheres*. Weber believed that individuals have a genetic predisposition to rational choices based upon self-interest, but that this is acted upon throughout life by a variety of forces, including the mores specific to social situations and cultures, learned values, and *nonrational* factors unique to each individual.

The critical social theory of Jürgen Habermas (b. 1929) addresses a multitude of philosophical, metaphysical, and sociopolitical topics, many based upon his conception of the *public sphere*. His approach integrates philosophical and social scientific methods. Habermas’s conception of rationality is essentially teleological, linking reason to fulfillment of innate urges and needs. Dialectical engagement between individuals and society by way of *communicative action* is oriented toward fulfillment of collective needs. Habermas describes *rationality* as an evolutionary learning process by a society, the product of interpersonal discourse rather than solitary reasoning processes. His

interest lies less in how *knowledge* is constituted than in “how speaking and acting subjects acquire and use knowledge.” His *discourse theory* depicts application of rationality to collective learning.

Some findings of social psychologists studying groups find that the tendency toward conformity in groups illustrates human *irrationality* rather than rationality. An example is Irving Janis’s (1918–1990) concept of *groupthink* (first published in 1972), illustrated by such events as the Bay of Pigs invasion of Cuba in the 1960s and, more recently, decisions related to Iraq and its former leader Saddam Hussein. Groupthink demonstrates that highly cohesive groups are prone to abandon rational decision-making processes to maintain unity. Studies of groupthink evidence the positive role conflict, properly managed, can perform in promoting group reasoning and rationality. Classic studies of group behavior such as Solomon Asch’s 1953 line-length experiment, Stanley Milgram’s 1961 obedience-to-authority studies, and Philip Zimbardo’s 1971 Stanford prison experiments demonstrate a disturbing tendency for members of groups to abandon logical and moral reasoning to follow the crowd or an authority figure. Research in this area is ongoing.

Recent Perspectives on Rationality

Many organizations are interested in models of practical rationality that can further critical and near-constant decision-making processes. In *real-world* application, constraints such as limited resources (especially time to arrive at a conclusion) and, in small-group decision-making, the necessity for individuals to cooperate selection and implementation, that purely rational, logical operations are not particularly effective. A quasi-logical model, *bounded rationality*, first theorized by James March and Herbert Simon in 1958, offers *satisficing* as an alternative to the *optimizing* approach, which searches for the ideal solution. In satisficing, a *good enough* solution is the goal. Simon observes that intuitive processes and experience-based knowledge—which are neither logical nor illogical—are valid elements of workable decisions.

For the French historian, philosopher, and social critic Michel Foucault (1926–1984), the philosophical system that attains the power to determine what *knowledge* is becomes embedded in the philological

system (structural elements of language or *langue*). In this way, episteme acquires the power to constrain and bound what is right or good to think or know. This hobbles the evolution and vitality of rational understanding of the “lived experience of an individual.” Foucault’s notions of *bio-power* and *bio-politics*—wherein power systems that build upon established norms and received knowledge take control over bodies and entire populations. He extends this critique to those who allow themselves to be physically and mentally *disciplined* in this way.

The emphasis in Western cultures on the supremacy of logic also has been subjected to critique by feminist and critical-cultural theoreticians. Dennis Mumby and Linda Putnam take the standpoint of *critical organizational theory*, accepting elements of Herbert Simon’s (1916–2001) theory of bounded rationality as a valuable critique of *pure rationality*, but still finding it problematic because its core assumptions are rooted in the *male-centered patriarchal worldview* that overprivileges the rational, relegating the emotional or intuitive to inferior status. They call for accepting *bounded emotionality* as both a corollary and an alternative to bounded rationality; they urge a *rewriting* of the relationship between reason and emotion.

Scientific and technological advances in neuroscience and computer science call into question some old ideas about rationality and emotion prevalent in the Western tradition. Neurobiologist Antonio Damasio (b. 1944) foregrounds ongoing laboratory research into *affective neuroscience* and sees feelings as having a truly privileged status because they are emanations of the sense experience of the body. Thus, emotions are the *causal link* among events, experiential states, and rational thought.

Augmenting *truth* with *truthiness* (the Merriam-Webster word of the year for 2006, meaning “what one wishes to be true rather than what one can prove to be true”) is recognized as a practical 21st-century discursive strategy. Concurrently, some paths that began to diverge circa the 6th century B.C.E. appear now to be moving toward convergence. Scholarly and scientific studies increasingly find compatibility between Eastern and Western views, especially in terms of *phronesis*, or practical wisdom. Together with some acceptance of the emotional and intuitive as valid ways of *knowing*, experimental and theoretical studies find mindfulness and reasonableness to be forms of perception and sources of wisdom at least

as effective as focused reason and logical processes. Weick and Putnam outline some of these claims in their (2006) article “Organizing for mindfulness: Eastern wisdom and Western knowledge.”

REALISM IN MATHEMATICS

The most general, least controversial, and consequently also least informative description of the doctrine of mathematical realism is the view on which mathematical objects (such as numbers, sets, right triangles, and tensors) are *real* (in the sense of not made up, either deliberately or unconsciously, by human subjects). To get a sense of why the doctrine is interesting enough to merit an entry here and substantive enough to remain the topic of ongoing debate among mathematicians and philosophers of mathematics, it is helpful to explore some of its more specific, and thus more controversial versions and their consequences, and to consider implications of the discussion of mathematical realism for realism *simpliciter*.

Mathematical Platonism

For better or worse, mathematical realism has long been associated with the classical Athenian philosopher Plato (427–346 B.C.E.), who in his dialogue *Meno* famously has his mentor Socrates lead an untutored slave boy through a series of basic geometric proofs. Since Socrates claims simply to have asked questions with a view toward soliciting what his interlocutor already knew, without ever instructing him in any way, he concludes that for all his lack of education the boy already knew some mathematics. Thus, by extension, we all have access to mathematical knowledge, though such access may remain merely latent. Although this argument appears to be about *mathematical knowledge*, it is also about *mathematical objects*, for it is in virtue of the actual mathematical objects to which the slave boy gains access that the insights he reaches are true and thus count as knowledge. The mutual dependence of accounts of mathematical knowledge with accounts of the nature of mathematical objects can give pause even to those philosophers inclined in general to treat metaphysics and epistemology as independent enquiries. We will return to this point later.

The metaphysical approach to mathematical objects associated with Plato's *Meno* is sometimes called mathematical *Platonism* to distinguish it from other forms of mathematical realism. For the

Platonist, mathematical objects are real, but of a very different order from other sorts of things commonly claimed to be real, including medium-sized physical objects, electrons, and nation-states. The Platonist takes mathematical objects to be eternal and unchanging, perhaps lacking even the property of being one day older today than they were yesterday. Platonism has the advantage of being consonant with the apparent universality of mathematical truths, including their invariance with respect to place and time. Among its disadvantages is the difficulty of explaining how creatures that are far from eternal and unchanging, such as human beings, could interact with mathematical objects in a way even remotely analogous to the ways in which we interact with other objects of knowledge. To see medium-sized physical objects, for example, we perceive the photons that bounce off their surfaces, enter our eyes, and onto our retinæ. Whatever faculty allows us to gain knowledge of eternal, unchanging mathematical objects, it would have to be very different from sight.

In modern philosophy of mathematics, one of the more influential mathematical Platonists is German mathematician, logician, and philosopher Gottlob Frege (1848–1925), who along with his contemporary Edmund Husserl (1859–1938) helped restore mathematical realism to prominence by critiquing the prevailing mathematical psychologism (on which mathematical objects are contingent aspects of human psychology) of the preceding generation. In an influential essay, Frege consigned mathematical objects to a *third realm*. Mathematical Platonists like Frege believe mathematical objects are real, and that they subsist neither in the realm of physical objects, nor in the realm of *mere* ideas, constituents of human psychology. They belong to a third realm of abstract objects.

Realism and Idealism

Since the 17th century, in metaphysics as well as in the philosophy of science, it has been customary to distinguish *realism* from *idealism*, treating the two doctrines as diametrically opposed. Some discussions even presuppose an excluded middle between the two doctrines, such that between them they must encompass the entire range of possible positions. In general, *realism* is the view that many ordinary objects of human cognition

are real, independent of human thought. In general, *idealism* is the view that all there is in the world are minds and their ideas. In the philosophy of science, *realism about x* is the view that x is real and independent of human thought, where for x we may insert any object of scientific knowledge or enquiry. In the philosophy of physics, for example, we find proponents of realism about electrons (and other particles resistant to direct observation), fields, and space-time. In the philosophy of biology, there are those who argue for realism about species and ecosystems. By contrast, *idealism about x* is the view that x is an aspect (or constituent, or function) of minds and their ideas, rather than of any mind-independent world. Such idealisms come in many different flavors. For a Berkeleyan idealist (after the British philosopher George Berkeley, 1685–1753), to be is to be perceived. Perception itself constitutes the perceived objects, which have no reality independent of their status as objects of perception. By contrast, while remaining agnostic about the existence of things-in-themselves (things as they are independent of our perception or knowledge of them), a post-Kantian, transcendental idealist (cf. the Prussian philosopher Immanuel Kant [1724–1804]) about space and time might assert that space-time, rather than an unfolding and expanding constituent of a cosmos far older than and largely indifferent to minds, is instead a necessary constituent of any finite intellect capable of experiencing any part of the cosmos in the first place.

Let us turn to *realism* and *idealism about mathematical objects*, say numbers. A realist about the natural numbers would presumably claim that they exist whether or not there is anyone in the universe who uses them for counting. By contrast, an idealist about the natural numbers would assert that the natural numbers are something like ideas in the minds of creatures that count. As this example helps illustrate, the distinction between realism and idealism in mathematics gives us reason to doubt that realism and idealism are anything like polar opposites. If minds and their ideas exist—if they are real—then the idealist about natural numbers is not denying their reality *per se*. Viewed a certain way, Frege's third-realm Platonism is both a kind of realism and a kind of idealism: Numbers are real, *and* they are ideas. Whereas minds may entertain and manipulate such ideas, the existence

of the ideas themselves is not contingent on the existence of the minds engaging with them. Again, mathematical ideas belong not to the realm of mind-independent physical objects, nor to the intracranial or social realm of merely human ideation and communication, but to the (third) realm of immutable abstract objects.

In light of such considerations, cautious discussions of the merits of realism in mathematics are better-off setting out from the distinction between *realism* and *antirealism*, rather than realism and idealism. Some brands of mathematical Platonism may count as varieties of both realism and idealism. Furthermore, there are important antirealist platforms that may well fail to count as varieties of idealism. These include mathematical *nominalism*, *fictionalism*, *instrumentalism*, and *conventionalism*, along with positions combining elements of two or more antirealist approaches.

Benacerraf's Problem

As noted earlier, the domain of mathematics gives pause even to those philosophers of science otherwise inclined to treat metaphysics and epistemology as independent branches of enquiry. In this respect the philosophy of mathematics has much to teach the philosophy of science. An account of mathematical objects that leaves them unknowable, strangling mathematical knowledge in the crib, would be unacceptable; the whole point of such an account is to help explain mathematical knowledge. Conversely, an account of mathematical knowledge that made the objects of mathematical knowledge into something too strange or impossible would be suspect by virtue of its incompatibility with any answer to the question, what is it that mathematicians have knowledge of? At least in mathematics, there appear to be checks and balances between epistemology and metaphysics, a prospect that philosophers of science studying other scientific disciplines might do well to consider.

In his famous 1973 paper, "Mathematical Truth," Paul Benacerraf articulated the tension between reasonable if seemingly conflicting demands on any philosophical account of mathematical knowledge in a way that continues to shape this conversation. To count as knowledge, mathematical beliefs must be (at least) true and

justified. Let an account of the truth of sentences count as a stand-in for an account of the truth of beliefs. On this assumption, Benacerraf claims, the best available theories of truth are variations on the *correspondence theory*, on which sentences are true just in case the objects corresponding to their nouns are in fact arranged in ways corresponding to their predicates. But by 1973, while continuing to accept truth and justification as individually necessary conditions for knowledge, analytic philosophers no longer held them to be jointly sufficient. Thanks to the American philosopher Edmund Gettier, beliefs worthy of being called *knowledge* now had to be not only true and justified, but also *caused in the right sort of way by the objects of belief*. This further stipulation is sometimes called the *causal condition* for knowledge. If truth in general is correspondence, then the truth of mathematical theorems and beliefs should properly be understood as a function of correspondence with mathematical objects. Such correspondence, in turn, presupposes *realism about mathematical objects*: If the objects weren't real, they couldn't correspond with anything in language, or anything in the minds of knowing subjects.

Mathematical theorems are not, however, merely contingently true, in the way it is contingently true, as I write this, that I am wearing a blue T-shirt. They appear to be *necessarily* true; that is, invariant with respect to time and place. So if they are true by virtue of correspondence with mathematical objects, *where are those objects*? Perhaps they reside in Frege's third realm, a realm of nonspatiotemporal abstract entities. If so, Benacerraf argues, this raises a further problem, for on the best available epistemologies, the causal condition is a necessary condition for knowledge. Satisfying the causal condition, however, requires the interaction between the epistemic subject and the object of knowledge. With *ordinary* objects of knowledge, such interaction seems unproblematic: I interact with my car by visually perceiving the light bouncing off its rust-pocked surface, hearing its misfires, or smelling its burning engine oil. By way of my senses, my car *causes* me to have beliefs about it, such as my belief that it is time for it to stop being a car and become scrap. How, though, do I imagine I might causally interact with third-realm entities? I can see three oranges in the usual way, by photons that bounce off their surfaces,

and I can likewise see three apples. However, the number three itself, the property of threeness, or the pure set of cardinality three, do not seem to be visible to me, or otherwise accessible to my ordinary senses.

The Austrian mathematician Kurt Gödel (1906–1978) posited that our access to mathematical objects must be mediated by a faculty he called *mathematical intuition*, like perception in some ways, though not dependent on sensation. Leaving aside the questions of how such a faculty might arise or what would make it reliable, there remains the fundamental problem of how spatiotemporally bounded creatures such as ourselves could ever gain access to the nonspatiotemporal residents of the third realm. More recently, the American philosopher Penelope Maddy has argued that the role Gödel envisioned for mathematical intuition could be played by ordinary perception. Consider visual perception. We claim to see cars, meerkats, and broccoli stalks by virtue of our ability to perceive photons that bounce off their surfaces onto our retinæ. In such interactions we only ever directly engage with the proximal surfaces of the objects in question and never with the whole objects themselves. If we are nonetheless prepared to allow that we perceive those objects, Maddy argues, then there is no good reason for denying that we perceive (certain) mathematical objects. Maddy's approach to mathematical realism addresses Benacerraf's problem by moving mathematical objects from the third realm squarely into the first, where reside other objects of perception.

Indispensability

Consigning mathematical objects to the first realm would not by itself force them into the same category as medium-sized physical objects. Consider another sort of first-realm denizen about which realism appears perfectly warranted, even if direct observation is impossible. Protozoa are single-celled creatures too small to see with the unaided eye, though they can be seen under sufficient magnification. Electrons, however, are not merely too small to see. According to our best current physics, they are unobservable in principle. Yet we are justified in believing in electrons, because their existence is indispensable to the coherence of the very same current physics that decrees them

unobservable. For its part, such physics does not want for observational support. Physics is an empirical science, founded in evidence. Although that evidence does not include the direct visual inspection of electrons, it does include, for example, the observational records of Robert Millikan's oil-drop experiment, whence the magnitude of the unit charge of the electron was first extrapolated. American philosopher Willard V. O. Quine's 1968 essay "Epistemology Naturalized" is a canonical source for this argument that we are justified in believing in the reality of electrons—or indeed in other observationally challenged entities—because they are indispensable to our current best empirical science. An extension of this argument in support of realism in mathematics seems perfectly natural. If indispensability-in-science militates for the reality of electrons, neutrinos, fields, and the Big Bang, it should perhaps weigh even more heavily in support of the reality of integers, real numbers, complex numbers, sets, right triangles, and finite Abelian groups, all of which play pivotal roles in articulating well-confirmed scientific theories.

A brand of realism founded primarily in arguments from the indispensability of mathematical objects in science (sometimes called the *Quine–Putnam indispensability arguments*) may be classified as *indirect realism*, as distinct from a *direct realism* founded in direct perceptual or intuitive access to the objects of knowledge. Another argument sometimes adduced in support of indirect realism is exemplified by Hungarian American mathematician Eugene Wigner's reflections on the *unreasonable effectiveness* of mathematics in the physical sciences. Math works. It works so astonishingly well, in fact, that its effectiveness would be nothing short of miraculous if mathematics were not somehow *about something physical*—if it did not at some level represent fundamental facts about the physical universe. At first blush, indispensability arguments and unreasonable effectiveness arguments may look like close cousins. However, the unreasonable effectiveness arguments accommodate one perplexing historical observation more easily ignored by advocates of the indispensability arguments. The history of mathematics offers numerous examples of entire branches of mathematics developed decades or centuries in advance of their applicability to any

empirical science. For example, the discovery of non-Euclidean geometry is typically dated to about 1830, when Nicolai Ivanovich Lobachevsky (1792–1856) and Janós Bolyai (1802–1860) published seminal papers. By contrast, physicists did not reach consensus about the non-Euclidean character of space-time until after the promulgation of Albert Einstein's theory of General Relativity in 1915. Though the unreasonable effectiveness argument does not by itself explain how pure mathematics can forge so far ahead of its scientific application, it also offers no objections. By contrast, for an indirect realist relying on indispensability arguments for the reality of mathematical objects, the apparent ability of mathematicians to gain knowledge of mathematical objects well in advance of any (indirect) scientific evidence of their reality is inexplicable.

Proof

Let us conclude this entry with one final persistent problem for realism in mathematics. This problem affects several varieties of mathematical realism, but for ease of exposition we shall focus on indirect realism, as explained in the preceding section. For the indirect realist, an argument for the reality of a given collection of mathematical objects Γ (gamma) might turn on the indispensability of Γ in articulating current scientific theory. However, such arguments rarely if ever carry any weight in pure mathematics, who instead rely on *mathematical proof*. In an earlier example, the plausibility of indispensability arguments for mathematical realism turned on an analogy between physical unobservables such as electrons and mathematical objects such as numbers and sets. Due consideration for the importance of mathematical proof in establishing mathematical knowledge immediately shows the limitations of this analogy. It seems likely that there is no single, universal scientific method. Nonetheless, whatever methods underwrite arguments for the existence of electrons seem unlikely to bear any resemblance to the mathematical proofs whereby one might demonstrate the existence of transfinite cardinals greater than $\aleph_0$. Part of the problem is that mathematical proofs, and the mathematical knowledge they underwrite, have long been thought to be *a priori* (prior to experience or based on reason alone).

Empirical science, almost by definition, is a *posteriori* (grounded in experience). However, even a conclusive argument in support of mathematical empiricism (the view that mathematical knowledge is *a posteriori*) would still have to contend with the methodological disparity between mathematics and the (other) empirical sciences.

Alternatively, we might allow consideration of the reality of mathematical objects to take a backseat to the discussion of the importance of mathematical proof in the growth of mathematical knowledge. One possible outcome of this approach is a very different sort of mathematical realism from any of those considered thus far. Let us say, for example, that my house is very real. It is eminently physical, as witnessed by the fact that my homeowner's policy attaches a value to the possibility that it might burn to the ground. But it is not *natural*. It was built—not by me, to be sure, but by human beings. Understood as a kind of mathematical realism, *mathematical constructivism* treats mathematical objects as the very real but also intentional products of human labor: the labor of mathematical proof.

Conclusion

For all the problems facing realism in mathematics, the view continues to have its share of champions. One factor in its continued prominence is the sense that one ought to trust the scientific experts and defer to their practices. In mathematics, the scientific experts are practicing mathematicians, who are often observed talking about their objects of enquiry, be they imaginary numbers or *n*-dimensional knots, *as if they were real*. If the experts think of them as real, who are we nonexperts to challenge them? In the philosophy of mathematics, mathematical Platonism is often asserted, without evidence, as the nearly unanimous position of professional mathematicians. Even if this claim were supported by an empirical survey of mathematicians, it does not change the fact that mathematical Platonism, and indeed mathematical realism in general, are not *mathematical* doctrines. They are *philosophical* doctrines. Mathematicians may well have philosophical opinions, including opinions about the reality of mathematical objects. Some printers employed by the U.S. Mint's Bureau of Printing and Engraving doubtless have views about

the reality of monetary instruments, too. Their views on ink viscosity as a function of temperature lie within their professional expertise. Their views on whether money is real are philosophical views, and as such they may or may not be interesting or compelling, but they merit no particular deference.

REALISM IN SCIENCE

See Scientific Realism

REASONING

Reasoning refers to the process of drawing inferences or conclusions from observations, facts, or opinions, often by means of logical rules. These inferences when performed correctly serve to advance knowledge, inform decision making and problem-solving efforts in fulfilling human goals of becoming better consumers of information. Reasoning in argumentation simply provides a rationale behind one choice over competing

choices. However, reasoning is not only for convincing others but also for evaluating arguments, and as such, it also has an epistemic function associated with thinking, cognition, and intellect. This entry briefly considers the historical development in the West of some of reasoning's important formal features, then considers the process of reasoning generally.

Etymologically the word comes from Medieval English (*res(o)un*), *reson*, *reisun* and the Old French word *raison* which are all translations from the original Latin stem *veri* meaning “think or reckon.” Thinking is, in essence, a précis of the general processes of cognitive thought, normally associated with human beings. Reckoning, on the other hand, is a specific cognitive process involving judgment and calculation, usually based around some formal system of measure. As a result, in the origins of the word *reason* is a mixture of two primary meanings at once general and formal. Consequently, it should not be surprising then that the development of meanings attached to the word *reason* have continued to mix both general and formal definitions to this one word, depending on circumstance, intent, and in some cases, convenience.

Reason is, by birth of meaning, also related to the development of the words *rate* and *ratify*. Inferences or conclusions are commonly described as being generated deductively or inductively. Additionally, there are numerous other types of reasoning. Because humans constantly draw inferences to justify beliefs and actions, the process or act of reasoning underlies our intellectual activities.

A History of Reasoning in the West

From its very birth, the word *reasoning* has remained both general and specific; formal and informal. This has not only resulted in the word suffering from a recurring lack of clarity and consistency of meaning, but at the same time this has made the word highly attractive for incorporation into philosophical ideologies.

Antiquity

Although before the time of Plato, very little was written about how we reason, it is inconceivable to think that processes and creations such as

arithmetic, algebra, and the Pythagorean theory dating back as early as 4000 B.C.E. existed without the use of reason. However, most attention to the beginning of process of reasoning is credited to the 5th century B.C.E.

The death of the tyrant Thrasybulus in 338 B.C.E. created a need for citizens in ancient Greece to know how to conduct themselves in court so as to recover property that had been seized by the government during the Peloponnesian War. For a price, the Sophists fulfilled that need. The Sophists were itinerant teachers in Athens and the surrounding area who taught, among other things, rhetoric—the art of persuasive speaking. The early Sophist Protagoras, born around 480 B.C.E., taught that knowledge could only be the result of sense perceptions. Protagoras believed that the only reality that existed was that which was expressed by individuals.

Whereas the Sophists often argued with the purpose of winning a case, Plato demonstrated that the use of argument was a method of discovering truth. Plato saw discussion as a way to clarify and organize thought. He also recognized the importance of imagination. He believed that imagination could replace reason when reason fails to supply the necessary connection between the ideal and the actual.

Although Plato did not write specifically about the exact way to reason effectively, he used the teachings of Socrates to illustrate effective arguments. The general methods used by Socrates were called *dialectic*. Dialectic, or the use of dialogue, is a means of intellectual investigation. In most of Plato's surviving works, he has Socrates as a foil for some popular philosophy, often propounded by a Sophist. His method was to ask leading questions, which ultimately demonstrated the fallacy of the particular belief under investigation. Plato's student Aristotle (384–322 B.C.E.), however, took a different approach to philosophy. Aristotle was very interested in perception. He was also concerned with finding ways of making one's perceptions more trustworthy. Aristotle's greatest accomplishment may have been his extensive conceptual development of categorical logic and the syllogistic argument.

The study of logic progressed very little for almost 1,000 years after Aristotle. Famously, the German philosopher Immanuel Kant (1724–1804)

said that it had not advanced at all since then. The Romans were masters at influencing others using the tools of logic and oratory. The idea of the learned man in the Roman world was the citizen-orator. Argumentation formed the basis of rhetoric. Rhetoric was composed of invention, arrangement, style, memory, and delivery, commonly referred to as the canons of rhetoric. The first two were closely related to argumentation. Even so, these modes of reasoning were principally those Aristotle had codified.

The Middle Ages

During the Middle Ages, or medieval period, the dominant social and educational institution was religion. As a result, rhetoric became associated with preaching. After the destruction in 1258 of Baghdad, the capital of the Abbasid Empire at the time, and the subsequent reconquest of Spain by Christian forces, there was very little advance in the study of reasoning. An exception was the development of supposition theory. Supposition theory embraced those properties of linguistic expressions necessary to explain truth, fallacy, and inference, the three core concepts of logical analysis. Peter Abelard (1079–1142) revived human reason as an effective tool for the discovery of truth. A sharp dialectic practitioner, he effectively confronted the predominant realism of the day and replaced it with his own conceptualist philosophy. Conceptualism rejected the reality of universals. Roger Bacon (1214–1294) was an early pioneer of scientific inquiry, expanding the methods that lie at the heart of modern science—experimentation and induction. Equally significant, Peter Ramus (1515–1572) popularized everyday logic. He also introduced the practice of dividing the canons of rhetoric so that invention and arrangement were associated with philosophy. Thereafter, rhetoricians were less involved with argument and more interested in style (gesture, delivery, figures of speech, etc.).

By the late 16th and early 17th centuries, reason quickly developed into a word implying formal systems of argument and thought processes. Suddenly reason, no longer meant simply thinking and reckoning but was regarded as a formal system of thinking and reckoning. By the mid-17th century, reasoning took on the added meaning as

a formal system of proof of thinking and reckoning. No longer was the act of following a certain system or procedure of thinking and/or reckoning sufficient; proof is also required.

The Age of Reason, or the Enlightenment

The 18th century, often referred to as the Age of Reason or the Enlightenment, witnessed a significant change in the way Westerners viewed themselves, the pursuit of knowledge, and the universe. Previously held concepts of conduct and thought could now be challenged both orally and in writing without fear of one's being denounced by the church as a heretic and punished, sometimes even being publicly executed by fire. This was the beginning of a more open society in which individuals were at liberty to pursue individual happiness and freedom, with the power of reason advocated as the primary source for legitimacy and authority. The dominant concepts of the medieval world were being abandoned both politically and socially. Concurrently, extensive changes were occurring in scientific thought and exploration. New ideas were developed, and people were eager to explore these ideas, freely. Immanuel Kant defined enlightenment as the liberation of man from his self-caused state of minority. Minority was defined as the incapacity to use one's knowledge or insight without the direction of another. Reason, philosophically, became regarded as the ability to form and operate upon concepts in abstraction, narrowing information to its basic content, without understanding and explanation.

The Age of Reason saw the introduction of the Scientific Revolution and various progressions of new schools of thought. Dualism, advocated by the French philosopher René Descartes (1596–1650), taught that God (mind) and man (nature) were distinct. Baruch Spinoza, a Dutch philosopher of Sephardic Jewish origin, introduced the idea of *pantheism*—that God and the universe are one—and further that God was a substance consisting of infinite attributes. Believers in Deism, described as the religion of reason, rejected Christianity as a body of revelation, mysterious, and incomprehensible. The Age of Reason gave rise to attacks on basic religious beliefs, rejection of God, and denial of miracles. In an attempt to

dissociate themselves from the mysticism of the Middle Ages, some thinkers during the Age of Reason applauded intellect and scorned spirit. God was believed to be unknowable, if He existed at all, and there was no need for divine communication or revelation. Nature was revelation enough, showing all that needed to be known about God. Human beings were now free to postulate their own theories of existence.

Sir Frances Bacon (1561–1626) rejected Aristotelean logic and Scholasticism in favor of a new framework for discovery, published in his *Novum Organum* in 1620. The new approach consisted of the careful conservation and collection of data, their correct interpretation, and experimentation. *Port-Royal Logic* was another important textbook of logic, published anonymously in 1662. It was written in simple language, contained many new notions, and was highly popular. The French mathematician Blaise Pascal (1623–1662) is presumed to have contributed to the Port-Royal textbook. In collaboration with Pierre de Fermat (1601–1665), he also developed probability theory, which later gave birth to statistics.

Since the time of Descartes, logic has meant formal, symbolic logic. Descartes had an enormous impact on logic. He instituted the idea of systematic doubt. He searched for the basis of reasoning—that which could be accepted axiomatically, without doubt. He found one idea that met that criterion: *I think, therefore I am* (in Latin, *cogito ergo sum*), which he wrote in French as *je pense, donc je suis*). Descartes inserted one other thing into logic—mathematics. He reasoned that God exists from a consideration of Euclid's exposition of geometry. He required that reasoning must proceed from unassailable axioms to conclusions. And then he translated position and motion into mathematical entities.

These ideas were to remain dominant in the sciences and in logic for the next 300 years. Reasoning became identified with formal logic. People began looking for ways to translate informal reasoning into formal logic and, thereby, to infuse reasoning with the certainty of formal thought. Science began looking for axiomatic bases for their investigations. Argumentation became the demonstration of self-evident proof. Other significant thinkers during this period

were Thomas Hobbes (1588–1679), a contemporary of Descartes and the founder of scientific materialism and ethical hedonism; John Locke (1632–1704), who believed that ideas are the products of experience and reflection on those experiences, in other words, reason; and David Hume (1711–1776). Hume proposed that science relies on facts; that things happen in an orderly sequence of causes and effects; that nature is uniform and things are associated naturally on the basis of similarity, proximity, contrast, and temporal association.

The 19th Century

By the 19th century, the word *reason* had become associated with, and entrapped by, the formal system of argument and proof called *logic*. Reason could no longer stand on its own; it had been conquered by the forces of logic. Free thought was no longer to be viewed as identical with reason. Reason was to be regarded as a formal system of thought and reckoning associated with logic. Common sense was no longer to be associated with reason, which had been clearly shown not to rely on a similar definition. Notable contributors to this way of thinking included the English polymath John Stuart Mill (1806–1873) who, in an effort to provide a firm basis for scientific reasoning, formalized inductive logic in his book, *A System of Logic* (1843). His work in logic influenced later logicians. The English mathematician George Boole (1815–1864) noticed a similarity between algebra and logic and developed a calculus of reasoning which was published in his *An Investigation of the Laws of Thought*. It later became known as two-valued or Boolean algebra and became the basis for the mathematics and logic used by digital computers.

The 20th Century

The 20th century saw a number of new philosophical schools of thought, including logical positivism, analytic philosophy, phenomenology, existentialism, postmodernism, and poststructuralism. Some of the notable contributors of reasoning during this period included John Venn (1834–1923), who invented the eponymous diagrams that make syllogistic logic so much easier

to analyze. Friedrich Ludwig Gottlob Frege (1848–1925) invented and axiomatized predicate logic. He was a major advocate of logicism, the position that arithmetic is reducible to logic. David Hilbert (1862–1943) laid the groundwork for formalism, the idea that mathematics is a meaningless exercise, a game, using symbols according to formal rules which are agreed to by consensus *a priori*. The developments in formal logic by Kurt Gödel, Alan Turing, Alonzo Church, and others undermined that program but led to important advances in understanding the distinction, and connection, between mathematical and logical inference. The entire discipline of recursion theory, the basis for much of computer science and our general understanding of modern algorithms, is an outgrowth of this work. Additional contributors to our understanding of reasoning about empirical matters include Karl Pearson (1857–1936); Albert Einstein (1879–1955); Karl Popper (1902–1994); C. L. Hamblin (1922–1985); Douglas Walton (1942–); Thomas Kuhn (1922–1996); and Stephen Toulmin (1922–), who held that formal logic is inappropriate as a model for argumentation. He developed a new and more adaptable model for nonformal reasoning. Toulmin also developed a way to diagram arguments that remains widely in use today. In contrast to Toulmin, others who were disenchanted with linguistic formalism attempted to preserve formal aspects of reasoning, but by different means. Toward the end of the 20th century, Jon Barwise (1942–2000), and his many collaborators and those influenced by him, focused on *formal* aspects of visual reasoning and inference.

The Process of Reasoning

The process of reasoning consists of the following course of action: We make observations. From our observations, we establish facts and/or theories. From facts/theories, we draw inferences. From our inferences, we make assumptions. We use our observations, facts/theories, inferences, and assumptions to form opinions. From our opinions, we then create arguments to defend our opinions. We use analyses to critique our opinions as well as other people's observations, facts/theories, inferences, assumptions, opinions, and arguments.

The Dominant Types of Reasoning

Good arguments derive from two major types of reasoning: deductive reasoning and inductive reasoning.

Deductive Reasoning

Deductive reasoning happens when one works from the more general information to the more specific. As it relates to research or argument preparation, sometimes this approach is called the *top-down* approach because researchers start with a very broad range of information and then work their way down to a specific conclusion. Deductive reasoning can also start with an assumed hypothesis or theory. The hypothesis or theory may be well accepted, or it may be somewhat faulty. Nevertheless, for the argument, it is not questioned. Deduction is also used by scientists who take a general scientific law and apply it to a specific case, as they assume that the law is true. Deduction can also be used to test an induction by applying it elsewhere, although in this case, the initial theory is assumed to be true only temporarily. The goal of deductive reasoning is to arrive at a valid chain of reasoning, in which each statement holds up to testing, but it is possible for deductive reasoning to be both valid and unsound.

The Greek philosopher Aristotle, considered the father of deductive reasoning, wrote the following classic example:

All men are mortal.

Socrates is a man.

Therefore, Socrates is mortal.

In Aristotle's example, sometimes referred to as a syllogism, the conclusion or premise of the argument—that all men are mortal and that Socrates is a man—is self-evidently true. Because the premises establish that Socrates is an individual in a group whose members are all mortal, the inevitable conclusion is that Socrates must also be mortal.

Inductive Reasoning

Inductive reasoning works the opposite way and typically only assigns probabilities to its conclusions. It draws conclusions or inferences from

observations in order to make generalizations. For example, our experience so far is that polar bears are white, and we might use induction to infer with high probability that indeed all polar bears are white. Inferences can be done in four stages:

Observation: Collect facts without bias.

Analysis: Classify the facts, identifying patterns of regularity.

Inference: From the patterns, infer generalizations about the relations between the facts.

Confirmation: Testing the inference through further observation.

Inductive reasoning is sometimes referred to as the *bottom-up* approach. Arguments from inductive reasoning can include part to whole where the whole is assumed to be like individual parts; extrapolations where areas beyond the area of study are assumed to be like the studied area; and predictions where the future is assumed to be like the past. Inductive reasoning is commonly seen in the sciences when people want to make sense of a series of observations. Isaac Newton, for example, famously used inductive reasoning to develop a theory of gravity. Using observations, people can develop a theory to explain those observations and seek out disproof of that theory. Another excellent example of this process in action is the discoveries and works of the naturalist and evolutionary biologist Charles Darwin (1809–1882). He made some observations about how the types of finches vary from each other across the Galapagos archipelago. After some thought and reasoning, he saw that these populations were geographically isolated from each other and that the differences between the subspecies varied over distance. He therefore proposed that the finches all shared a common ancestor, and had evolved and adapted, by natural selection to exploit vacant ecological niches. This resulted in evolutionary divergence and the creation of new species, the basis of his famed work *On the Origin of Species*. This was an example of inductive reasoning, as he started with a specific piece of information and expanded it to a broad hypothesis. Science then used deductive reasoning to generate testable hypotheses and test his ideas.

Tacit Versus Explicit Reasoning

Reasoning occurs at two different levels of awareness: tacit and explicit reasoning processes. Tacit processes that facilitate reasoning occur without conscious intervention and outside awareness; they typically do not require attention. Explicit reasoning processes, on the other hand, occurs within the sphere of conscious awareness. We are aware not only of the outcome of our thinking (as with tacit processes) but also of the processes themselves. Such thinking is often described as *strategic*. It typically requires effort and it allows us to bypass the relatively slow accumulation of experiences that underlie tacit learning. Hence, reasoning involves both tacit (unconscious) and explicit (conscious) processes.

Additional Types of Reasoning

Many types of mental activity used to draw conclusions fall under one or the other of those two classes. For example, in analogical reasoning, an analogy for a given thing or situation is found, where the analogy is like the given thing in some way. Other attributes of the analogical situation are then taken to also represent other attributes of the given thing. Our brains work by patterns and association—if a perception fits roughly into an existing pattern, then the existing pattern may be taken as definitive. To use an analogy, start with a target domain where you want to create new understanding, find a general matching domain where some things are similar to the target domain, find specific items from the matching domain, and transfer attributes from the matching domain to the target domain. Thus, A is like B. M is in A. N is in B. So M is like N. And in cause-and-effect reasoning, one appeals to known or suspected causes either to predict or to explain effects. Cause-and-effect reasoning is generally persuasive as it helps answer the question *why* something happens, making a statement objective and rational rather than a blind assertion.

In addition to the varieties of reasoning that conform to either inductive or deductive inference, Charles Sanders Peirce (1839–1914), and before him William Whewell (1794–1866), suggested another distinct class, *abductive inference*. The general idea is to infer a complete pattern from isolated instances of the pattern. In that way, it is similar to

inductive reasoning. The difference can be illustrated by an example: It was known through the exercise of inductive reasoning where various planets would be observed to be at various times, using Ptolemaic or Copernican systems. But Kepler inferred abductively that, in fact, the orbits of the planets were ellipses. This inference to an entire orbital structure was unprecedented and functioned differently from traditional induction.

RECEIVED VIEW OF THEORIES

See Theories, Syntactic Conception of

REFUTATION

Refutation (R) can be defined as a procedure to confront a theory with evidence proving this theory is wrong or false. R is a concept rooted in an important tradition of thought, namely

falsificationism, according to which the paramount requirement for a theory to be considered as scientific is that the theory must be refutable. A theory that is not refutable by any conceivable event is nonscientific. R is, therefore, a criterion for distinguishing between statements or systems of statements that are scientific versus other statements, such as those that are pseudoscientific, metaphysical, or religious in nature. There is disagreement, however, as to the meaning of what it is for a theory to be confronted by evidence, as well as what should be the criterion of demarcation between science and not-science. This entry presents the competing views on this topic and discusses the links between refutations and other arguments concerning falsificationism, such as conjectures, falsifiability, and verisimilitude.

Procedures to Confront a Theory With Evidence

The meaning of a theory's being confronted by evidence is a contested topic, marked by various competing views. Because there are no very precise boundaries between these views and because the term R is embedded within falsificationism, it is helpful to map an account of these approaches. Moreover, there exists an open-ended discussion as to whether a basic translation between those approaches might be adopted to allow for a temporary suspension of the general problem of incommensurability.

Keeping this in mind, however, it may be claimed that there are several variations of four types of approaches on the sort of procedures used to confront a theory with evidence, namely, *falsificationism*, *verificationism*, *confirmation holism*, and *pragmatism*. These approaches differ in many ways. One of the most important differences between falsificationism, verificationism, confirmation holism, and pragmatism has to do with how each of these perspectives conceives the act of confronting a theory with evidence. Briefly, from falsificationism's viewpoint, to confront a theory with evidence is formulated as testing this theory with certain possible results of observation that are incompatible with that theory. If observations show that the predicted effect is definitely absent, then the theory must be considered as refuted. In a different way, verificationism posits that confronting a theory with evidence involves identifying

propositions that can be verified by true statements based on observation. Therefore, confronting a theory with evidence is defined as the verifiability of this theory in terms of observation statements. The third approach, confirmation holism (also called the *Duhem-Quine thesis*), claims that for any putative falsification, it is always possible to preserve a scientific hypothesis by revising auxiliary hypotheses in its stead. Finally, pragmatism calls for practical decisions and practical arguments rather than for theoretical reasons or evidence to refuse or accept a theory.

These differences concerning what it means to confront a theory with evidence are related to other differences among these views. One such difference lies in their lines or criterion of demarcation between scientific statements and other sorts of statements—for instance, philosophical. From a different criterion of demarcation to R, that is, verification, Ludwig Wittgenstein tried to show that all so-called *philosophical propositions* were actually *nonpropositions* or *pseudopropositions*, in that they were senseless or meaningless. This idea involved a characterization of science as opposed to philosophy. According to Wittgenstein, all genuinely meaningful propositions must be fully reducible to *elementary* or *atomic* propositions; these are simple statements that describe possible states of affairs and can, in principle, be established or rejected by observation. To confront a theory with evidence means that the theory can be verified by statements based on observation. This implies that the propositions that legitimately belong to science are deducible from true observation statements; statements that may possibly fall within the province of science can possibly be verified by observation statements. These statements coincide with the class of all genuine or meaningful statements. According to this approach, therefore, verifiability, meaningfulness, and scientific character all coincide.

Wittgenstein's verifiability criterion was intended to play the part of a criterion of demarcation. This criterion of demarcation was verifiability or deducibility from observation statements. In this sense, verificationism is a rival view to falsificationism: Falsificationism looks for observation statements that can override the initial hypothesis (and if they are not found, the hypothesis will have greater verisimilitude and, therefore, it will be closer to the truth). By contrast, in

verificationism, it is considered that observation-based statements are to be added that corroborate the hypothesis, with which it is inductively consolidated. Thus, verificationism clashes with falsificationism in the function assigned to observation statements. From falsificationism's viewpoint, no scientific theory can ever be deduced from observation statements or can be described as a truth function of observation statements.

In distinction from both of the foregoing approaches, confirmation holism (also called *epistemological holism*) is skeptical of the very possibility of testing a theory. Confirmation holism states that it is impossible to test a scientific hypothesis in isolation, since an empirical experiment requires assuming as true one or more auxiliary hypotheses (or background assumptions). The hypothesis in question is itself incapable of making predictions. In fact, the consequences of the hypothesis typically are based on the auxiliary hypotheses from which predictions derive. This argument prevents a theory from becoming conclusively falsifiable through the empirical world if auxiliary hypotheses are not tested, which is an improbable task since auxiliary hypotheses sometimes include one or more scientific theories.

Because this thesis was formulated by Pierre Duhem (1861–1916) and Willard Van Orman Quine (1908–2000), it is also known as *Duhem–Quine thesis*. Its implications for the possibility of confronting a theory with evidence are critical. Because a single hypothesis or theory can only be tested by its relation to other hypotheses or theories, this leads us to the problem against which confirmation holism warns us: One might believe that the results of a test have refuted a hypothesis or scientific theory when actually these results have not done so at all. Instead, it can be argued that those results conflict with the predicted effect because any other hypothesis or theory is false. This argument prevents a theory from becoming conclusively falsified.

From a distinctive epistemological outlook that contrasts with those of falsificationism, verificationism, and confirmation holism, pragmatism offers what this tradition calls the *pragmatist maxim*. This can be defined as a rule for clarifying the contents of hypotheses by tracing their practical consequences. Instead of *true* theories, pragmatism prefers to speak of theories that perform

as if they were true. True propositions, then, are those that enable us to function well. True statements are ones that function successfully as instruments. From pragmatism's viewpoint, propositions are evaluated by the merits of the practices that are involved in our use of them.

Consequently, confronting a hypothesis or theory with evidence involves identifying its practical consequences. Pragmatism argues that the *clarification* of a scientific hypothesis implies we have the information we need for testing it empirically. Testing theories involves carrying out experiments, understood as the performing of rational actions. If the hypothesis is not true, then the experiment will fail to have some predetermined practical effect. If the hypothesis is wrong, we will observe *practical differences* between our theoretical expectations and what the experiment shows us.

Falsificationism proposes R as criterion of demarcation; R distinguishes science from pseudoscience. Contrary to the requirement of searching for elements that refute a theory, the most characteristic element of pseudoscience is the incessant stream of confirmations—that is to say, of observations that *verify* the theories in question. Pseudoscience always involves confirmatory information. Whatever happens always confirms it. Thus, its truth appears to be manifested. Classic examples of supposed pseudosciences are three theories: Karl Marx's theory of history, Sigmund Freud's psychoanalytic theory, and Alfred Adler's individual psychology. According to the characteristics of pseudoscience, every conceivable case (or observation) could be interpreted in light of Adler's theory, or of the Marxist theory, or equally of Freud's theory. It would be difficult, if not impossible, to think of any social or human behavior that could not be interpreted in the terms of any of these theories.

This idea may be illustrated by a classic example of *self-verification* for both the Adlerian theory and Freudian theory through their *explanations* of two kinds of human behavior, which drew attention to the philosopher Karl Popper (1902–1994): that of a man who pushes a child into the water with the intention of drowning the child; and that of a man who sacrifices his life in an attempt to save the child. Each of these two cases can be explained with equal ease in Freudian and in Adlerian terms. According to Freud, the first man suffered from

psychological repression, while the second man achieved what Freud called *sublimation*. According to Adler, the first man suffered from feelings of inferiority (perhaps the need to prove to himself, in that he dared to commit a crime), and so did the second man (whose need was to prove to himself, in that he dared to rescue the child). It is precisely this feature—that these theories always are confirmed—that constitutes its logical weakness. Different observation statements lead to confirmation of the same theory.

As an example of science (and a counterexample of the pseudosciences), Popper mentions the endeavored attempt to refute just one prediction of the theoretical physicist Albert Einstein's gravitational theory, made by Arthur Eddington's 1919 expedition. Einstein's hypothesis stated that light was attracted by heavy bodies (such as the sun), precisely as material bodies were attracted. The prediction was that light from a distant, fixed star, which had an apparent position that was close to the sun, would reach the earth from such a direction that the star would seem to be slightly shifted away from the sun. This is something that cannot normally be observed, since such stars are rendered as invisible in the daytime by the sun's overwhelming brightness; however, during an eclipse, it is possible to take photographs of them. If the same constellation is photographed at night, one can measure the distances in the two photographs and check for the predicted effect. The findings of Eddington confirmed Einstein's gravitational theory or, rather, one of the hypotheses of that theory.

The central issue is that Einstein's theory was incompatible with certain possible results of observation. If observations showed that the predicted effect was definitely absent, then the theory would simply be refuted. Every scientific theory is a prohibition: It forbids certain occurrences from happening. The more a theory forbids, the better it is. This is quite different from the pseudoscience that was previously described: When the theories in question are compatible with the most divergent human behavior, it is practically impossible to describe any human behavior that might not be claimed to be a verification of these theories.

A second issue is that only the theory of Einstein—in opposition to the Freudian theory, Marxist theory, and Adlerian theory—was heavily exposed to a high

risk of being refuted. An important disadvantage for a scientific theory is that it is easy for a nonscientific theory to be *confirmed* or *verified*. This occurs for almost every theory, if their adherents look for confirmations. At the same time, there are degrees of testability. Some theories are more testable, and some theories are more exposed to refutation than others; they involve, as it were, greater risks.

Some definitely testable theories, even when they are found to be false, are still upheld by their followers. The followers rescue the theory from R through some *procedures*. Examples of these procedures are introducing ad hoc some auxiliary assumption or re-interpreting the theory ad hoc in such a way that it avoids R. These decisions, however, have a fundamental cost for the theory: destroying, or at least decreasing, its scientific status.

The Marxist theory of history, despite the serious efforts of some of its founders and followers, ultimately adopted those practices. In some of its earlier formulations (e.g., in Marx's analysis of the character of the *coming social revolution*), the predictions were testable and were in fact falsified. Instead of accepting the refutations, however, Marxists reinterpreted both the theory and the evidence in order to make them agree.

The Freudian and Adlerian theories were in a different class. They were simply nontestable and irrefutable. There was no conceivable human behavior that could contradict them. Typically, supporters of both theories reinterpreted their hypotheses ad hoc in such a way that they escaped refutation. This does not mean that both theories did not present valid viewpoints; however, it does mean that the *clinical observations*, which some analysts naively believe confirm their theory, cannot supply such confirmations.

These considerations lead to the problem of establishing a criterion of demarcation among the statements or systems of statements for the empirical sciences, as well as all other statements, such as religious, metaphysical, or pseudoscientific statements. The criterion of falsifiability was the Popperian solution to the problem of demarcation: statements or systems of statements, in order to be defined as scientific, must be capable of conflicting with possible or conceivable observations. In a different way, the criterion of verifiability claims that only those propositions that are deducible from true observation statements belong to the science.

Consequently, from the verificationism's viewpoint, the meaning of confronting a theory with evidence is established through true observation statements that can verify a hypothesis or theory.

Against falsificationism's position in favor of refutation (i.e., the criterion for testing a theory must be to prove that this theory is wrong or false), confirmation holism poses a criticism to Popper and his criterion of falsifiability: As the Duhem–Quine thesis argues, for any alleged falsification it's always possible to maintain a hypothesis by revising its auxiliary hypotheses.

Pragmatism also has implications in terms of the demarcation problem. A pragmatic approach to the line, or criterion, of demarcation would argue that while there are some core principles that one can use in distinguishing between science and nonscience, judgments and decisions about the scientific status of a hypothesis or theory depend, in part, on practical goals and concerns. In a manner distinct from other views on the demarcation problem, pragmatism claims in favor of considering both theoretical statements and practical statements as lines to distinguish science from not-science.

Induction, Conjectures, and Refutation

Following the Scottish philosopher David Hume's (1711–1776) criticism of the logical basis of induction, Popper was led to his theory of conjectures and refutations (or theory of trial and error). Popper's thesis—following Hume's ideas on induction—asserted that our attempts to force interpretations upon the world were logically made prior to the observation of similarities. This, in turn, had an important consequence for the philosophy of science; scientific theories were not the digest of observations, but they were inventions—that is, conjectures boldly presented for trial and to be eliminated, if they clashed with observations.

In this sense, Hume gives a causal explanation about the fact that we believe in laws or in statements that assert regularities or constantly conjoined events, by asserting that this fact is due to a *custom* or *habit*—that is, the custom or habit of believing in laws or regularities. It can therefore be said that, like other habits, our habit of believing in laws is the product of frequent repetition of the repeated observations that

things of a certain kind are constantly conjoined with things of another kind. The central idea of Hume's theory is repetition, based on similarity (or *resemblance*).

In the wake of Hume's theory, Popper noted that only repetition-for-us, based upon similarity-for-us, can have any effect upon us. We must respond to situations *as if* they were equivalent, viewing them as similar and interpreting them as repetitions. Thus, the cases were repetitions only from a certain point of view. This meant that, for logical reasons, there must *always* be a point of view, such as a system of expectations, anticipations, assumptions, or interests *before* there can be any repetition; point of view, consequently, cannot be merely the result of repetition.

However, if this is so, there can be no valid logical arguments that allow us to establish that the instances, of which “we have had no experience,” resemble instances of which “we have had experience.” Consequently, even after observation of the frequent or constant conjunction of objects, we have no reason to draw any inference regarding any object beyond instances of which we have had experience. In other words, an attempt to justify the practice of induction by an appeal to experience must lead to an infinite regress. As a result, we can say that theories can never be inferred from observation statements or rationally justified by them.

Having refuted the logical idea of induction, Hume was faced with the following question: how do we actually obtain our knowledge if induction is a procedure that is logically invalid and rationally unjustifiable? There is only one possible answer: we obtain our knowledge by a noninductive procedure. Conjectures, counterexamples, and refutations were solutions that falsificationism proposed for the tricky basis of induction.

A *conjecture* is a proposition that is unproven. A conjecture stands in contrast to a *hypothesis*, which is a testable statement based on accepted grounds. In mathematics, a conjecture is an unproven proposition that appears to be correct. Sometimes, a conjecture is called a *hypothesis* when it is used frequently and repeatedly as an assumption to prove other results. For example, the Riemann hypothesis is a conjecture from number theory that (among other things) makes predictions about the distribution of prime

numbers. Few number theorists doubt that the Riemann hypothesis is true.

In mathematics, any number of cases that support a conjecture, no matter how large, is insufficient for establishing the conjecture's veracity, since a single counterexample would immediately invalidate the conjecture. Formal mathematics is based on *provable truth*.

In terms of logic, especially in its application to mathematics and philosophy, a *counterexample* is an exception to a proposed general rule. For instance, consider the proposition that "all apples are small." Because this statement makes the claim that a certain property (smallness) holds for all apples, even a single example of a big apple will prove it to be false. Thus, any big apple is a counterexample to "all apples are small." More precisely, a counterexample is a specific instance of the falsity of a universal quantification (a "for all" statement).

Conjectures disproven through counterexamples are sometimes referred to as *false conjectures*. A classical example of a false conjecture is the Pólya conjecture. Regarding number theory, the Pólya conjecture stated that *most* (that is, 50% or more) of the natural numbers, less than any given number, have an odd number of prime factors. The conjecture was posited by the Hungarian mathematician George Pólya in 1919 and was proven as false in 1958 by C. Brian Haselgrove. The size of the smallest counterexample is often used to show how a conjecture can be true for many numbers and still be false.

Refutation indicates that a scientific theory in a *conjecture process* must be proven as valid. Clearly, refutation and falsifiability are related concepts. Often, they are used as interchangeable notions. However, there seems to be a subtle difference between the two. One does not need to have an observationally testable theory to be able to effectively refute a scientific theory. Refutation and criticism are the basis for all gains in knowledge. According to Popper, we *only gain knowledge from our mistakes*. It is, therefore, *not* observation that initiates the growth of knowledge. Thus, contrary to the inductivist scheme, scientific discovery does not need to begin with observational evidence. In other words, scientific enterprise always advances in relation to a set of ideas that seems to be inadequate and worth trying to improve.

Refutation, Falsification, and Verisimilitude

Falsification and verisimilitude concepts play roles in the notion of truth, an uneasy idea that Popper avoided in his earliest writings. Instead, it was less risky to accept that every theory is an open-ended hypothesis. Then, *ipso facto* it must be at least potentially false. For this reason, it was more acceptable to assert that a theory that is falsified is false and is known to be such, as well as a theory that replaces a falsified theory (because it has a higher empirical content than the latter and presents what has falsified it), is a *better theory* than its predecessor. However, Popper came to accept Alfred Tarski's (1901–1983) reformulation of the correspondence theory of truth, and he integrated the concepts of truth and content to frame the metalogical concept of *truthlikeness* or *verisimilitude*. Thus, Popper argued that a *good* scientific theory has a higher level of verisimilitude than its rivals. He also explicated this concept by referring to the logical consequences of theories.

Scientists should therefore be interested in theories with highly informative content because such theories possess a high predictive power and are, consequently, highly testable. However, if this is true, then, as paradoxical as it may sound, the more *improbable* a theory is, the better it is scientifically. This is because the probability and informative content of a theory vary inversely. The higher the informative content of a theory, the lower its probability will be; the more information a statement contains, the greater the number of ways it may turn out to be false. Informative content, which has an inverse proportion to probability, is in direct proportion to testability.

The Popperian view proposes two methods of comparing theories, in terms of verisimilitude, the qualitative and quantitative accounts. In the qualitative approach, it is asserted that assuming that the truth-content and the falsity-content of two theories t_1 and t_2 are comparable, we can say that t_2 is more closely similar to the truth or corresponds better to the facts than t_1 , if and only if either: (1) the truth-content but not the falsity-content of t_2 exceeds that of t_1 ; or (2) the falsity-content of t_1 but not its truth-content exceeds that of t_2 .

Here, verisimilitude is defined in terms of subclass relationships: t_2 has a higher level of

verisimilitude than t_1 , if and only if their truth (and falsity-content) are comparable through subclass relationships and if either of the following are true: (1) t_2 's truth-content includes t_1 's and t_2 's falsity-content, if it exists, is included in, or is the same as t_1 's; or (2) t_2 's truth-content includes or is the same as t_1 's and t_2 's falsity-content, if it exists or is included in t_1 's.

In the quantitative approach, verisimilitude is defined by assigning quantities to contents, and the index of the content of a given theory is its logical improbability (given again that content and probability vary inversely). Formally, then, Popper defines the quantitative verisimilitude, which a statement, "a," possesses by means of the formula:

$$Vs(a) = Ct_T(a) - Ct_F(a),$$

where $Vs(a)$ represents the verisimilitude of a , $Ct_T(a)$ is a measure of the truth-content of a , and $Ct_F(a)$ is a measure of its falsity-content.

The utilization of either method of computing verisimilitude shows that even if theory t_2 , with a higher content than a rival theory t_1 , is subsequently falsified, it can still legitimately be regarded as a better theory than t_1 . Here, *better* is understood as meaning that t_2 is *closer* to the *truth* than t_1 . Thus, scientific progress involves, in this view, the abandonment of partially true but falsified theories.

Lakatos's view on scientific progress contrasts with Popper's argument in favor of verisimilitude. Imre Lakatos claims that merely defining the aim of science as verisimilitude is not enough. One needs to be able to identify this progress when it occurs. It is not enough to say that novel corroboration may be a "good reason to conjecture" that we are getting closer to the truth. We need a firm connection between the two.

On the other hand, the role of R in scientific progress is completely different for these two philosophers of science. In Lakatos's terms, scientific progress is defined as predicting some *novel fact*—that is, a *hitherto unexpected fact*. According to Popper, novel facts are a bit of an add-on, since much of the empirical burden is carried by falsification and refutation. For Lakatos, who wanted to decrease (to zero) the role of negative evidence and refutation, the entire burden of scientific progress is carried on the shoulders of novel facts.

Lakatos asserts that the importance of novelty is a clear counterexample of scientific progress; if we really know P1: "Swan A is white," then Pw:

"All Swans are white" represents no progress because this may only lead to the discovery of similar facts, such as "P2: Swan B is white." Hence, so-called *empirical generalizations* constitute no progress. A *new* fact must be improbable or even impossible in the light of previous knowledge.

From the Popperian view, scientific theories might change in the future, as we find an observation that refutes existing theory. However, until a new fact comes into existence, we are justified in believing in the knowledge gained through the conjecture and refutation process. Induction is neither needed nor desired in this formula for growth of knowledge.

Finally, conjecture and refutation are not merely the ways in which science progresses. For example, Popper sees direct ties between evolution through natural selection and the growth of scientific knowledge. In fact, growth of scientific knowledge may be thought of as a special case of biological evolution. From a biological or evolutionary point of view, science or progress in science may be regarded as a means used by the human species to adapt to an environment, to invade new environmental niches, and even to invent new environmental niches. Therefore, all of the knowledge, even the *knowledge* embodied in DNA, can be conceived as stemming from the conjecture-and-refutation process.

RELATIVE CONSISTENCY

Relative consistency is a theoretical construct the utility of which arises mainly in the fields of mathematics and logic, although its use has been extended (through the use of metaphor and analogy) to other, more loosely defined contexts. At its most basic level, relative consistency is a relation that may hold between different components of a theory. It will sometimes be the case that a theory cannot be objectively proven; in most cases, this will also mean that the individual components of the theory also cannot be proven, either because no objective standard or method of verification exists, or because it does exist but is unavailable. In such cases, it may still be possible to show that the individual parts of the theory are consistent with one another, or *relative to* one another. If this can be done, then, as shown in the following sections, one can prove the relative consistency of the theory even if the theory itself cannot be objectively proven.

Consistency

A theory is considered to be consistent if it is free from any contradictions. There are two main methods of determining whether or not a theory contains one or more contradictions. The first method is syntactic, and the second method is

semantic. The *syntactic method* asks us to determine that there is no formula that can be constructed using the theory's axioms such that both the formula and its negation can be proven. If there is, then the theory is not consistent, but if there is not, then the theory is consistent under syntactic analysis.

Semantic analysis of a theory's consistency asks us to determine whether there is a model of the theory within which all of the theory's formulas are demonstrably true. If it is possible to show such a model, then the theory is semantically consistent. If no such model can be shown, then the theory is not semantically consistent.

Within the realm of mathematics, the method used to determine whether a theory is consistent is usually referred to as a *consistency proof*, a special type of the broader category of mathematical proofs.

Completeness

The completeness of a logical or mathematical theory is intricately bound up with its consistency. A theory is said to be complete if the theory itself is consistent but none of the theory's extensions is consistent. One way that this can be determined when one is working in the realm of classical logic is by examining each sentence that can be composed in the language of the theory. If each of these sentences, or its negation, exists within the theory already, then the theory meets the criteria for completeness.

Gödel and Incompleteness

Kurt Gödel, an Austrian mathematician who lived from 1906 until 1978, was active in the fields of logic and philosophy and is best known for his work on the concept of incompleteness. Essentially, Gödel was able to demonstrate that any theory of arithmetic that is complex enough will be, in a sense, incomplete at the most basic level because it will not be possible for the theory to be both consistent and complete—only one or the other will be attainable. The reason for this is difficult to explain without lengthy mathematical proofs, but it has to do with the concept of *recursion*, also known as *self-reference*. A sufficiently complex theory can never be both consistent and

complete because in order to be complete, it would need to contain a full copy of itself. This seems simple enough until we recall that inside that copy of itself there will need to be another copy of the theory itself, nested within the parent copy—otherwise the copy would be incomplete. This paradoxical dilemma will continue to replicate itself downward, layer upon layer, without end, never attaining completeness.

Some who have sought to carry on Gödel's work have attributed to it a semimystical significance, suggesting that it is symbolic of the ultimately ineffable nature of the universe, and affirming the suspicions of mystics that there are some things in the universe that are simply unknowable. That point is certainly open for debate, but other applications of Gödel's work are not in controversy. The most salient takeaway from Gödel's work on incompleteness is that when an arithmetical system—or a set of theoretical models that has been translated into mathematical symbols—is complex enough, it will be impossible to prove the consistency of that theory on its own terms. This is because the system of the theory will always be incomplete (due to the recursion problem noted earlier), and therefore, the consistency of the complete system is not possible to verify. This creates special problems for mathematicians and logicians seeking to establish the consistency of a theoretical model. We would like to establish models that are both complete and consistent, yet Gödel predicts that this is impossible using conventional definitions of what it means to be complete and consistent. The solution to this dilemma, when it eventually appeared, was both simple and elegant: create and apply a new definition of consistency that, while different in significant respects from the traditional, objective concept of consistency, is still persuasive evidence of a theoretical model's utility. This type of consistency is known as *relative* because its focus is not on how objectively consistent a theory is but on whether it is consistent with another theory already known to be consistent.

The Value of Relative Consistency

At this point, it should be clear why relative consistency is of interest in the analysis of mathematical and logical theories: Because it is not possible

to demonstrate consistency of sufficiently complex theories, we instead evaluate them for relative consistency.

It is useful to recall from the study of logic that a formal system is inconsistent if it is possible for us to use the system to prove both an axiom and the negation of that axiom. As Gödel made clear, it can be extremely challenging to prove that a system is consistent, given the potentially very large number of statements that can be formulated using the language of that system, and given the essentially incomplete nature of very complex systems. What is often easier to do is to prove that a system is consistent in relation to another system, the consistency of which has already been verified.

For example, if one were to develop a system of axioms A, and there also exists a system B, the theorems of which are the same as the axioms of A, then by comparing the two, we could determine that A and B are relatively consistent, that is, they are consistent relative to one another rather than consistent with an objective standard. A historical example of this dynamic can be seen in the case of the Russian mathematician Nikolai Ivanovich Lobachevski (1792–1856). Lobachevski was the first to publish his research into hyperbolic geometry (also referred to as *non-Euclidean geometry*, or simply *Lobachevskian geometry*). Lobachevski's geometry is congruent with Euclidean geometry except for one point. Where Euclid's fifth postulate states that, for a given line and a point not on the line, there is only one line that passes through the point not on the line but does not intersect with the line, Lobachevski developed a geometry in which more than one line meets these requirements. Lobachevski's work was validated in part through the application of principles of relative consistency.

This process is known as a *relative consistency proof*. Relative consistency proofs can become extremely complicated, since they require one to create a theory interpretation into another theory, so in recent years, there has been a move toward accomplishing this task with the use of computer programs whenever possible. This requires the user to enter the axioms of the theories being compared into mathematical statements capable of being manipulated by the computer software. Once this has been done, the computer can

evaluate the axioms for consistency relative to one another by breaking the theories down into simpler subsystems, analyzing these, and then “putting the pieces back together.”

Relative consistency is widely used as an alternative to proving completeness or consistency. Gödel himself used relative consistency to show the independence of the Axiom of Choice, a part of set theory, and the same method was also used to prove the Continuum Hypothesis, which concerns the sizes possible for infinite sets of numbers. Gödel’s career was unusual inasmuch as he not only became aware of the nature of a huge obstacle to progress in logical and mathematical theory—incompleteness—but he also developed an ingenious workaround for this obstacle using relative consistency to force consistency proofs to “pull themselves up by their bootstraps,” in other words demonstrating consistency toward each other even when objective consistency could not be established.

Applications of Relative Consistency

As mentioned earlier, relative consistency had its conceptual origins in mathematics and logic, but it has been adapted to other fields and incorporated into the vernacular of everyday speech. From its original, technical meaning, it has evolved to the point where it is often used to describe the extent to which a set of results make sense when considered together. For example, if we were to collect test scores from students at a high school and analyze them, without even being aware of it, we would be checking for discrepancies—places where particular parts of the data do not make sense when compared with other parts. We might find that over 80% of students scored no higher than a C in algebra but that over 90% of students received a grade of B or an A in trigonometry. If either the algebra grades or the trigonometry grades were viewed in isolation, there would be nothing remarkable about them to draw our attention. When they are considered in relation to one another, however, they appear to be inconsistent because trigonometry is traditionally seen as a much more difficult topic than algebra. Assuming that is the case here, why would most people do worse in the easier class than they did in the more difficult one?

This raises a related use for relative consistency concepts outside of logic and math: test construction and validity. When authors set out to create an assessment instrument to be administered to a population of subjects in order to measure one or more qualities the subjects may possess, their challenge is to create questions that actually test the attribute the designers intend to assess rather than some unrelated characteristic. One of the most important methods used to ensure that this happens is to review the results of the instrument for relative consistency. An interesting example of a question that tested something other than had been intended (the true target was students’ knowledge of vocabulary) involved a multiple-choice question asking students which would be more appropriate to go fishing on: a yacht, a schooner, a canoe, or a catamaran. Undoubtedly, the person who drafted the question thought that it was a perfectly reasonable way to assess students’ nautical terminology. However, when the test administrators noticed that students in certain parts of the country tended to score poorly on this question, issues of relative consistency were raised, and further study was devoted to understanding the reason for the discrepancy. It turned out that students from lower income neighborhoods and students who lived in landlocked states had very little knowledge about different types of watercraft and thus were unable to discern the correct answer to the question. Thus, the question was really testing a type of knowledge that only a certain type of student would have rather than knowledge all students could reasonably be expected to have. As in the previous example, if the question had been reviewed in isolation, there would have been no way of understanding why it was being answered incorrectly. But, by viewing it in relation to students’ performance on other questions, test administrators were able to identify the issue responsible for the drop in scores on that question.

S

SCIENTIFIC REALISM

Scientific realism (SR) constitutes a variety of realism that emerged primarily with the work of theorists Karl R. Popper and Mario Bunge. SR asserts that a real external world exists and that we can know it through the scientific method. SR holds a strong commitment to the idea that scientific theories have a privileged epistemic status compared with other forms of knowledge such as ordinary knowledge, intuition, or hermeneutics. SR also maintains that scientific theories yield knowledge of unobservable aspects of the world. The basic principles of SR are as follows: (1) The external world exists independently of the cognitive subject (ontological realism); (2) it is possible to know the world (epistemological realism); (3) some propositions refer to facts and some factual propositions are approximately true (semantic realism); (4) all factual knowledge is incomplete and fallible (fallibilism); (5) in principle, any factual proposition is perfectible (meliorism); (6) the best approach to explaining the world is the scientific method (methodological realism). These principles are discussed in the sections that follow.

SR has similarities and differences with two other varieties of realism: *naïve realism* and *critical realism*. Naïve realism accepts principles (1) and (2). Critical realism accepts principles (1), (2), (3), (4), and (5). SR holds the principles (1), (2), (3), (4), (5), and (6). A distinctive attribute of SR over other forms of realism is its methodological realism. Methodological realism holds that the

best approach to study entities, forces, and processes, whether observable or unobservable, is to use the scientific method. Using the scientific method, we can reasonably construe scientific theories as providing knowledge. This is true for both natural and social facts.

SR is an amalgamation of two rival classical philosophical traditions: rationalism and empiricism. SR promotes the construction of theories competent to account for empirical data, as well as the exploration of data in light of theory. Hence, it discourages unrestrained speculations as well as mindless data gathering. SR emphasizes the constructive nature of ideas in particular concepts, problems, rules, and experimental designs. It stresses the justification—conceptual, empirical, or both—of all claims to knowledge. However, it is fallibilist as well as meliorist. Namely, it recognizes no final truths except in logic and mathematics. Lastly, SR is systemic: It places every question and every answer into some system, such as description, classification, theory, or a well-designed empirical research project.

Realism and Antirealism

Antirealism rejects one or the other of these two realist theses: (1) The external world is material and exists by itself and (2) science can capture that reality. Roughly speaking, antirealism holds that scientific explanation is inherently limited because science seeks only relations and does not inquire into the nature of objects, or because its epistemological scope is fundamentally limited. Moreover,

some antirealists contend that claims about unobservable things have no literal meaning at all. There are, however, several kinds of antirealism.

Transcendentalism adds that every entity has an immutable essence beneath its properties and relations and that those essences, which escape reason as well as experience, are apprehensible with nonscientific means: with intuition of some sort or other. *Phenomenalism* refuses to tolerate essences just because they are nonphenomenal, but it agrees with transcendentalism that science is limited to establishing relations, whether among phenomena or among fairly directly observable traits or facts, but that it never gets to the *things themselves*, which are mere *metaphysical constructs*. Realism holds that experience is not definitive but should be accounted for in terms of a much wider but indirectly knowable world: the set of all existents.

Phenomenalism, by contrast, asserts that the endeavor of science consists of collecting, describing, and systematizing phenomena without inventing diaphenomenal or transobservational objects—such as quarks, mental representations, and social cognition. For realists, experience is a type of event: Every single experience is a fact happening in the cognitive subject, which is in turn regarded as a concrete system (e.g., a brain)—but one having expectations and a set of knowledge that both alter and enrich their experiences. Therefore, realism encourages the development of theories going beyond the systematization of experiential items and requiring consequently ingenious test procedures.

SR rejects all types of irrationalism, from neo-Platonism to existentialism and *postmodernist* relativism–constructivism, passing through intuitionism and pragmatism. Against these philosophies of science, SR asserts that no knowledge is possible without the combination of reason and experience.

SR and Other Schools of the Philosophy of Science

The philosophy of science in SR is a sort of synthesis of realism, rationalism, and empiricism. SR asserts, as does realism, that there is an external world, that scientific research aims at depicting it, and that this is a never-ending enterprise because every picture of the world misses some of its traits

and adds others that are untrue. Simultaneously, SR claims, as does rationalism, that such pictures are symbolic rather than iconic, that logic and mathematics are a priori, and that signs are meaningless unless they stand for ideas. Finally, SR affirms, as does empiricism, that experience is a crucial feature for factual theories and procedures, that there can be no certainty in them, and that philosophy should adopt the method and standards of science. Therefore, SR marries its position to the successful reference of theoretical terms, including those for unobservable entities, processes, properties, and relations.

SR is an alternative to other major traditions in the philosophy of science. SR clashes with radical rationalism as well as irrationalism, with intuitionism and pragmatism, with classical positivism and logical positivism, and with constructivism–relativism as well as critical rationalism.

The radical rationalist believes we come to knowledge “a priori”—through the use of logic—and that this knowledge is, therefore, independent of sensory experience. In a different manner, SR emphasizes that experience with the external world is another source of human knowledge.

Irrationalism argues in favor of two theses in opposition to SR. First, irrationalism claims that intuition, instinct, feeling, or faith, rather than reason are the sources of human knowledge (epistemological irrationalism). Second, irrationalism holds that the universe is governed by irrational forces (ontological irrationalism). In contrast, SR asserts that reason (and not intuition, instinct, or faith) is the mental basis for scientific knowledge. Irrationalism, according to SR, is a philosophy that seeks reasons to justify irrationality, which is a contradiction on its own terms. On the other hand, and contrary to ontological irrationalism, SR asserts that the assumption that nature and culture are irrational has been largely refuted by the advancement of science. All of these arguments can also be said about the differences between SR and intuitionism.

Pragmatism claims that thinking about problems should be based on dealing with a specific situation instead of on ideas and theories. In other words, pragmatism asserts that the meaning of concepts is to be sought in their practical bearings, that the function of thought is to guide action, and that truth is preeminently to be tested by the

practical consequences of beliefs. There is an epistemological difference between SR and pragmatism: according to pragmatists, prediction is all-important, whereas explanation is parasitic. Prediction is more valid than explanation in epistemic terms. A second difference between SR and pragmatism is about the aim of science: For pragmatists, the maximum value of a theory is its efficiency in relation to practical problems, whereas for a scientific realist the maximum value of a theory is to produce true descriptions of things in the world. Since theories can be applied to cognitive as well as to practical aims, therefore, SR and pragmatism are not two opposing enterprises. However, SR highlights that cognitive application of theories (e.g., explanation) precedes their practical applications (e.g., technologies).

Classical positivism, defined as positivism prior to the foundation of the group of philosophers known as the *Vienna Circle* in the early 1920s, holds that impressions of the senses provide direct knowledge of the world. A response from SR to classical positivism is that, for instance, the light provided by a source such as the sun does not indicate in a direct manner the composition and structure of the source. The light of the sun tells us nothing about the fact that the sun is composed mostly of hydrogen. Likewise, the light of the sun informs us neither that the hydrogen atom consists of a single electron, nor that the electron can be in any of infinite states, nor that the change from one state to another generates a photon. Therefore, the perception of light through the eyes and the brain does not tell us, by itself, anything about its composition. Such composition and structure are unobservable, and they need to be explained by a theory (provided by reason and not only by perception).

A second difference between classical positivism and SR is about the role of data in scientific inquiry. Classic positivism affirmed that data guide the whole sphere of scientific research. In a different manner, SR claims that data are neither used nor organized in any way, but also that a set of hypotheses is always used in a more or less explicit manner. Usually, the data are sought and produced in accordance with some hypotheses. These, in turn, are controlled by relevant empirical evidence. Neither the data nor the hypotheses have the final word in scientific research. What it

is true is that no perfect—completely exhaustive and accurate—explanation is ever achieved. Consequently, there are no final explanations.

The logical positivists, separating from their predecessors, claim to have overcome the dilemmas of realism/antirealism and materialism/idealism. In particular, they argue that the autonomous existence of an external world is a pseudo-problem. On the other hand, and like SR, most logical positivists reject religion and metaphysics. SR and logical positivists agree in considering that the physical world is either possibilities of perception or logical constructions derived from precepts. Logical positivism also adheres, however, to some of the theses of phenomenism. In particular, some of its members argued that the Copernican system of cosmology differed from the Ptolemaic system only in that it was another way of speaking. The major dispute between these two opposing theories about the organization of the planetary system is seen just as a problem of language on the part of the logical positivist. Whatever the reality was, it passed to the sidelines. This view places logical positivism far away from SR.

Critical rationalism, represented by the work of the Anglo-Austrian theorist Karl R. Popper (1902–1994), tries to assemble a theory of the proper assessment of sentences, that is, of the opportunity of proving the truth or falsity of some sentences. Popper begins with the fact that a theory is false if it contradicts a singular sentence describing some observation reports. Popper then affirms that such singular sentences are veridical, that is, truthful as opposed to illusory, so they may be used to create ultimate proofs of the falsity of some universal sentences. For instance, the singular sentence, “That swan is black,” if it is a true report of some observation, can be used to generate a final proof of the falsity of the universal sentence, “All swans are white.” But, he argues, proof of universal sentences or the demonstration that they are probable requires inductive inferences.

Inductive inferences have observations as premises and theories as conclusions. They are notoriously invalid but often are deemed unavoidable. As a consequence, no such putative proof can be valid. SR’s strong version, exemplified by the Argentine philosopher and physicist Mario Bunge’s oeuvre, apparently finds more affinity with those thinkers who emphasize the use of

formal methods and who futilely seek justification, than with those who deny the possibility of justification and deem the use of formal methods more limited than he does. As a corollary of this attitude, Bunge proposes to respond to difficulties first with small changes that preserve systems (or frameworks) and move to larger ones when these prove inadequate. This is the exact opposite of what Popper said, as he advocated that one should always prefer that theory which has the highest degree of falsifiability. These thinkers, however, disagree not about the aim of the philosophy of science, which is to improve critical standards so that the best possible theories are created and honed, but rather about the best means for doing that.

The constructivist-relativists deny the difference between thing and idea, between fact and fiction, and between law and convention. They deny the existence of objective truths and, therefore, they oppose the existence of transhistorical and transcultural truths. Conversely, SR holds that ideas and facts are different entities and that they exist independently of the observer. The facts are not confined to constructions of researchers. The most notable example is provided by mathematics, chemistry, and genetics: Their truths are independent of the culture and its conventions.

SR, Naive Realism, and Critical Realism

When referring to SR, scholars argue, more or less consistently, the following postulates: (1) Science aims to produce true descriptions of things in the world (or approximately true descriptions); (2) the best existing scientific theories are at least approximately true; (3) the central sentences of the best current theories are genuinely referential; (4) the approximate truth of a scientific theory is sufficient explanation of its predictive success; (5) the (approximate) truth of a scientific theory is the only possible explanation of its predictive success; (6) a scientific theory may be approximately true even if inferentially unsuccessful; (7) the history of at least the mature sciences shows progressive approximation to a true account of the material world; (8) the theoretical terms of scientific theories are to be read literally, and so read are definitively true or false; (9) scientific theories make genuine, existential claims; and (10) the predictive

success of a theory is evidence for the referential success of its central terms.

It is important to distinguish between a strong (or comprehensive) version and a weak (or restrained) version of SR. For instance, Bunge represents the comprehensive version. Jarrett Leplin represents the restrained version. However, sometimes the boundaries between the comprehensive version and the restricted version are diffuse. For instance, although some authors write about SR and identify themselves with SR, other authors define the former as *pragmatic*. Occasionally, critical realists' arguments overlap with restrained version of SR's arguments.

The strong version of SR includes the idea that values can be analyzed by science. This assumption, in turn, follows from the thesis of axiological realism: There are objective values such as health, peace, or equity. The strong version of SR (also known as *integral realism*) supports the thesis of moral realism: There are moral facts, such as unselfish versus selfish actions, and there are true moral principles, such as that unselfish actions promote peaceful coexistence. The restrained version of SR rejects both axiological realism and moral realism.

Naive realism is another kind of realism. In a different way than SR, naive realism claims that the senses provide us with direct awareness of the external world. Naive realism can be equated to common sense's realism: Perception exemplifies unmediated contact with the external world; examples of indirect perception might be seeing a photograph or hearing a recorded voice. Two classic versions of naive realism are the theory of knowledge of reflection and figurative language theory. Naive realists often argue that the multiple neurophysical processes by which we are aware of objects do not entail indirect perception. These processes merely establish the complex path by which direct awareness of the world arrives. The differences in the theory of knowledge between naive realism and SR seem to come from the fact that the first kind of realism does not recognize the crucial distinction, which the second kind of realism introduces, between primary properties (*noumena*) and secondary properties (*phenomena*). This ontological difference produces a number of epistemological differences between the two varieties of realism.

In terms of the theory of testing, SR also conflicts with naive realism's idea that theories are tested more or less like fertilizers. Consequently, for naive realists, the whole methodology of science would be reducible to statistics.

There is a much broader debate between SR and the third kind of realism, namely, *critical realism*. Critical realism constitutes a complex combination of two philosophical traditions, realism and constructivism, that emerges primarily with the oeuvre of Roy Bhaskar (1944–2014) and Wendy Olsen (1960–). For critical realists, natural and social phenomena do not exhaust the category of what really exists in the world. In the work of Bhaskar, there is an ontological distinction between what he calls the domains of the empirical, the actual, and the real. These ontological domains are recognized by most of the critical realists, who conceive of them as their own ontology of the natural and social world. Each of the three domains is relatively sovereign from the other two. The first two can be distinguished as follows: The domain of *the empirical* is made up of human sensory experiences and perceptions, while *the actual* refers to events taking place in the physical world. Perception can sometimes be misleading or unreliable. The third of Bhaskar's domains is *the real*. The real consists of those mechanisms and structures that have causal powers and whose generative capacity creates the order we see in observable entities. Lastly, the real is not the same as the empirical. The empirical gives us an avenue of entrée to the real, but only when the former is guided by theory. Empiricism makes mention only of experience (the empirical), but that events go far beyond what is experienced and that the domain of the *real structures* and other generative mechanisms requires a larger conceptual map of reality. Therefore, empiricism rests upon a deep confusion in terms of the critical realists. It conflates the *empirical* with the *real*, instead of separating them out carefully. Briefly, for the critical realist, the aim of science is the theoretical identification of things and their causal powers.

The literature of critical realism on ontology, epistemology, and methodology is huge, although it has been much more developed in the social sciences. Critical realism suggests a set of philosophical foundations for social research. Taken as a

whole, the methodological bases of critical realism have much in common with strong social constructivism but would strongly modify its underlying assumptions. On the other hand, critical realism has little in common with empiricism. Critical realists have presented a whole series of contributions to methodology. Among these, the most important are the focus on *ontic depth* and the proposal of a new logic of inference, namely, *retroduction*.

Ontic depth refers to having a conceptual map of the world's nature that allows for multiple layers, complexity, interweaving, and dynamic interaction of the sections of that world. *Retroduction* can be defined as the logic of inquiry espoused by critical realists and is the method used to move backward from an observation to the causes of that observation. Retroduction can be distinguished from other research strategies such as deduction or induction. Deduction develops specific claims from general premises. Induction develops general claims from specific premises. As a third mode of inference, retroduction explains events by postulating and identifying mechanisms that are capable of producing them. Strictly speaking, retroduction is not so much a formalized logic of inference as a thought operation that moves between knowledge of one thing to another, for example, from empirical phenomena expressed as events to their causes.

Critical realists suggest the importance of an ontic depth when they, for instance, urge the reality of social structures in the world. By carefully defining structures as real but difficult to observe, critical realists argue that it is possible to carry out many post-structuralist research practices without becoming committed to a markedly relativist or entirely constructivist ontology.

For instance, critical realism suggests that the concept of structure can have two different meanings. It can refer to an ensemble of various things whose relationships produce a single overall entity which *has* a structure. Examples include social structures such as an organization or a city, university as a social institution, the social norm's structure, or the class structure. A second conceptualization of structure emphasizes that the whole has *emergent properties* that differ from the properties of the objects contained by the structure.

The concept of *emergent properties* is very important for critical realists (and also for scientific realists). Emergent properties of a whole are varying over time, if it is a social structure (e.g., social values), whereas they might be somewhat constant over time within a specific physical structure (e.g., the planetary system). Another well-known example of an emergent property arises from the study of the brain: The mind is an emergent property of a brain. Critical (and scientific) realists propose that an ontological property of the things is emergence.

There are several important differences between critical realism and SR. A first difference is epistemological: For critical realists, methods and theory are not value-neutral (e.g., quantitative research is value-laden). A second difference is ontological: For critical realists, empirical regularities do not necessarily point out causality, and the absence of empirical regularities does not necessarily indicate the nonexistence of causality. Therefore, empirical regularities aren't a necessary condition to indicate causality.

Other difference emerges from the use of the term *the real*: For critical realists, *the real* refers to immaterial and impermanent objects which, *for a caused event* or *for a specific observer at a point in time*, are causal and very important. For instance, critical realists asserted that the reality of textually grounded objects was to be checked via the analysis of what social outcomes appeared to be caused by them. A social object (such as a narrative) that has effects can be seen as real. In SR terms, this would mean that narrative is conceived as an independent variable. At the same time, critical realists see narratives not as merely textual but as real social products of ongoing underlying social relations. In SR terms, this would mean that narrative is conceived as a dependent variable.

Philosophy of Science in SR

Contrary to widespread opinion, SR does not claim that our knowledge is accurate. It is sufficient that knowledge be partially true and that some of the falsehoods of our knowledge can be discovered and eventually corrected. Thus, SR postulates the thesis of fallibilism and the thesis of meliorism as two features inherent to science: All knowledge of facts is incomplete and fallible and

much of it is indirect (fallibilism); in principle, any approximation is perfectible (meliorism). Therefore, verifications with reality (the set of empirical tests) will demonstrate again and again that even more precise theories are, at best, more or less close approximations that can be improved.

SR asserts there are two types of properties: primary properties (or noumena) and secondary properties (or phenomena). In contrast, phenomenologists do not admit noumena, such as things or events that exist independently of perceptions (ontological phenomenalism) or elements that, although it considers that they exist, cannot be perceived (epistemological phenomenalism).

Scientific realists do not deny the existence of secondary properties (or *qualia*). In addition, SR postulates that qualia are very different from physical objects and their elementary properties. For instance, SR asserts that secondary properties emerge within a nervous system as a result of external stimuli. In consequence, scientific realists propose that qualia should be studied by psychology, psychophysics, and cognitive neuroscience.

The combination of ontological realism, epistemological realism, semantic realism, and methodological realism suggests a realistic axiology assessment that considers it as a process that occurs in a brain immersed in a social network. In turn, an axiology of this nature invites a realistic interpretation of social norms and rules to address social problems. Likewise, a realistic ethics suggests a practical philosophy that will help address the practical problems both efficiently and in accordance with moral principles. In order to be clear about what SR amounts to in the context of the philosophy of science, it is useful to understand it in terms of those three dimensions: an ontological dimension, an epistemological dimension, and a semantic dimension.

Ontological Theses in SR

Realistic ontology is the basis for an epistemology that encourages the study of real-world properties distinguishing primary properties from secondary properties. In turn, this stimulates a realistic epistemology that begins with a semantic theory of reference and factual truth. Semantic realism encourages such a methodology based on the scientific method. Therefore, it supports the

subject–object dichotomy and encourages the explanation of secondary properties through primary properties.

Ontological realism is the thesis that the universe, or reality, exists *in se et per se*, in and by itself. Ontologically, SR is committed to the mind-independent existence of the world investigated by science. This idea is best clarified in contrast with positions that deny it. For instance, the mind-independent existence of the world is denied by any position that falls under the traditional heading of *idealism*, including some forms of phenomenology, according to which there is no world external to the mind and, thus, independent of the mind. More common rejections of mind-independence stem from neo-Kantian views of the nature of scientific knowledge, which deny that the world of our experience is mind-independent, even if (in some cases) these positions accept that the world in itself does not depend on the existence of minds.

It is important to note that for SR's approach, human convention in scientific taxonomy is compatible with mind-independence. SR accepts the idea of a mind-independent natural kind structure of the world, at the same time that it also accepts that mind-independent properties are often conventionally grouped into a typology by scientific theories, that is, theoretical terms *transform* the external world to the cognitive subject.

Only a tiny part of reality has emerged, remains, and changes for us, but its existence does not depend on the knowing subject. The knowing subject is a real thing surrounded by other real things, most of which existed before the subject, and they did not need their help to exist. The SR proposes four grounds in support of its ontological realism: the arguments of physics, biology, cognitive neuroscience, and history.

The first argument is that fundamental physical laws are invariant under certain changes in frameworks, including observers. Frameworks are special physical systems that do not necessarily include humans. Biology's claim asserts that organisms, including bacteria and philosophers, extract nutrients and energy from their environment and they are provided with sensors for external signals. This is the reason why organisms die if they are completely isolated from their environment, and they face great risks when their sensors

perform poorly. The brain cannot exist without the world around it, from which it extracts not only nutrients but also the stimulation necessary for its normal development and functioning. The role of the environment in the development of a normal brain has been shown experimentally. The genome is not sufficient for the normal development of the brain: Stimulation from the external world is also needed. In short, environmental stimuli contribute heavily to the development of the brain. When these stimuli are absent, the brain fails to develop normally.

The argument of neuroscience can be summarized as follows: Mental functions are brain processes, some of which represent external events. Scent comes from an external signal. Sometimes the brain produces illusions or hallucinations: It sees *water in the desert* or it hears *voices*. On the other hand, no two people see the world exactly the same way, as no two brains have identical life stories. However, all people, even those who have severe autism, agree that there are certain things that exist by themselves, such as trees, buildings, and others.

Finally, the argument of history points out that all historical sciences, from geology to cosmology, to evolutionary biology, and to historiography, take the past for granted. Moreover, they assume that the study of the past cannot change the past. Constructivists could say that the past (not only their study) is a social construction. For SR that affirmation shows confusion between the past, history and its descriptions, and historiography.

Epistemological Theses in SR

Epistemologically, SR is committed to the idea that theoretical claims (interpreted literally as describing a mind-independent reality) constitute knowledge of the world. This idea contrasts with skeptical positions which, even if they grant the ontological and semantic dimensions of realism, doubt that scientific investigation is epistemologically powerful enough to yield such knowledge or, as in the case of some antirealist positions, insist that it is only powerful enough to yield knowledge regarding observables.

Epistemological realism can be synthesized, according to Mario Bunge, by one definition and six theses. The definition is this: If a thing is real,

this thing exists independently of the cognitive subject. Note that this definition cannot be a criterion of reality, since it does not tell us how to find out if that thing persists while we are not looking it. The six theses are as follows: (1) Reality is understandable, or better, you may know some facts, but usually in a partial and gradual manner; (2) indirect knowledge is deeper and is obtained by means of theories and indicators rather than through mere perception or intuition instantaneous; (3) almost certainly, sometimes we err, for instance, by using poor operational techniques, making false assumptions, or producing false data; (4) it is possible, in principle, to improve any given piece of knowledge, and make it more accurate or deep; (5) moderate pluralism: In principle, any set of facts can be presented by means of alternative hypotheses or theories; and (6) objective knowledge supported by solid tests and valid theories is superior to subjective intuition.

SR supports the so-called *explorer's argument*: Anyone who intends to explore a territory or investigate a thing, event, or specific process assumes that these things exist or may exist. Thus, the physicist who tries to find Higgs bosons with the aid of particle accelerators of high energy supposes the possibility that these particles, postulated by a theory, exist.

Semantic Theses in SR

Semantically, SR is committed to a literal interpretation of scientific claims about the world. According to SR, claims about scientific entities, processes, properties, and relations, whether they are observable or unobservable, should be construed literally as having truth-values, whether true or false. This semantic commitment contrasts primarily with those of so-called *instrumentalist epistemologies of science*, which interpret descriptions of the unobservable simply as instruments for the prediction of observable phenomena.

Semantic realism is the concept according to which: (1) Some propositions refer to (talk about) facts, and (2) some factual propositions are true to some extent. Thesis (1) is rejected by the textualists and deconstructionists, according to whom a symbol refers to other symbols. Radical skeptics reject thesis (2). Note the difference that semantic realism raises between reference and

representation. While tautologies, conventions, and statements of pure mathematics have referents, they do not represent anything in the real world.

Differing from the redundancy theory (the concept of truth is redundant since to state p is the same as claiming the truth of p), from the coherence theory (a proposition is true in a body of propositions if and only if it is consistent with the remaining constituents of this body), and from the correspondence theory (a factual proposition is true if and only if corresponds to [represents] the facts to which it refers), SR postulates the synthetic theory of truth.

The synthetic theory of truth can be summarized by a definition and a criterion of factual truth. The definition is this: Proposition p asserting fact b is true if and only if f occurs. The criterion of factual truth includes: (1) p is compatible with (and, exceptionally, equivalent to) the pertinent empirical evidence, and (2) p is consistent with the bulk of the relevant background knowledge. Note the distinction between the definition and the criterion of factual truth: the first tells us what is the truth and the second tells us how to identify it. The failure to distinguish between truth and evidence of truth is the source of some varieties of antirealism. One of them is the pragmatic assertion that there are no bridges between our theories and the world, because these theories can only describe the relevant evidence. According to SR, such confusion between reference and test is like confusing the bacteria with the microscope. This confusion also characterizes the verification theory of meaning, proposed by the Vienna Circle. According to SR, this theory is false: Measurements and experiments can tell us whether a hypothesis is true, not what this hypothesis means. Moreover, the meaning precedes the testing, because we need to know what a hypothesis means *before* designing proof of its truth value.

The *error argument* is another of the postulates of semantic realism. The very concept of scientific error, either conceptual or empirical, presupposes the real existence of the postulated entity. For example, a scholar can be interested in the number of crimes in a city. Then, the researcher seeks the reports on crimes in the police records. However, this number of crimes that the researcher believes

that there were in the city is wrong because many victims of such crimes, especially in countries where the police have poor performance (if they are not openly corrupt), do not report the crime to the police. There are victims who have not been included in the scholar's account. Consequently, those schools of philosophy that reject the concept of objective truth cannot use the concept of error understood as discrepancy between theory and reality.

Methodological Theses in SR

In the methodological dimension, SR holds two main theses: (1) The scientific method is the best approach to get the most objective, more accurate, and deeper truths about events of all kinds (methodological realism) and (2) this postulate applies to both natural science and social science (methodological monism). Postulate (1) is the more controversial in the debate between realists and antirealists. Postulate (2) is the most contested issue between SR and critical realism.

Opponents of methodological monism argue that subjectivity cannot be studied scientifically. They affirm that cultural or social sciences, unlike the natural sciences, must seek to *understand* (*Verstehen*) social facts rather than *explain* them (interpretivist thesis). To understand social facts, interpretivism's method proposes to find the *meaning* that actors give to their behavior. Natural facts, unlike social facts, are not guided by meaning. The different nature of social facts and natural facts must sustain an insurmountable methodological dualism between social sciences and natural sciences.

Methodological realism recognizes the differences between natural sciences and social sciences regarding their objects of study and the techniques to study them. However, methodological realism also argues that such differences do not represent any obstacle to the use of a general method in all sciences. To justify the latter assumption, methodological realism postulates that everything that exists encompasses a material dimension, including the meaning that individuals give to their behavior. Such meanings are manifested in processes occurring in the prefrontal cortex that are studied by cognitive neuroscience. Finally, methodological realism asserts that all researchers in all

sciences (natural and social) have similar brains, and all researchers in all sciences (natural and social) share the goal of finding objective truths.

SCIENTIFIC REVOLUTIONS

Scientific knowledge typically accumulates over time and transforms gradually over the course of years, as new studies and observations provide fresh insights into existing problems and ideas. Every so often, however, a powerful research finding or radically different proposition challenges

the foundations or assumptions that characterize the scholarly pursuits of the time, rendering some theories obsolete and opening up new pathways for inquiry. When this happens, it is referred to as a *scientific revolution*. Therefore, a scientific revolution constitutes a radical change in the conceptualizations that are accepted within one or more disciplines. In order to account for the fact that revolutionary ideas may also emerge in fields that are not considered strictly scientific, the term *conceptual revolution* is used in many contemporary contexts.

Changes in the knowledge base of a learned community occur normally over time, but what defines a revolution is a profound shift in perspective leading to new ways of thinking about old problems, new problems being defined as appropriate for study, or new processes being laid out for the pursuit of knowledge. According to philosophers of science, revolutions seem to follow specific patterns, are usually preceded by a period of crisis and uncertainty, and can be sparked by the work of people who are new to established intellectual traditions. Revolutionary ideas can stem from a variety of fields and often end up influencing the theoretical constructs used in more than one discipline.

In historical terms, we refer to the 16th and 17th centuries as encompassing a particular kind of scientific revolution—one that defined the modes of inquiry and the kinds of questions that would occupy scholars in subsequent centuries, directly shaping the scientific and industrial development of contemporary societies. It was during this time that the scientific method was formalized, the principles of rationalism were established, and the Enlightenment project emerged as a pathway for achieving progress, with special emphasis being placed on education, reason, and empirical research. Thus, the significance of the Scientific Revolution resided in its ability to impact not only scholarly practices but also people's common understandings about the world, the cosmos, and humanity's place in it. In later centuries, deep shifts in theorization and inquiry have continued to take place, accompanying new breakthroughs in science and research, and yielding new insights into a multitude of problems. The following sections discuss the process leading to scientific revolutions; the factors contributing to

the emergence of modernity and the scientific revolution of the 17th and 18th centuries in Europe; the nature and applications of the scientific method; the development of rationalism, empiricism, and the philosophy of science; and the 20th century's conceptual revolutions in the sciences, including the emergence of qualitative methods, critical theory, and the development of new disciplines.

The Emergence of a Scientific Revolution

A revolution is often brought about by a discovery or proposition that forces a scrutiny of previous assumptions: This may be prompted by staggering research findings, new technologies, or conceptual reformulations that cannot be disregarded. In many cases, a scientific revolution involves a breakthrough that transcends the scientific community. Among the prominent scholars who have written about the process leading to revolutions is Thomas Kuhn (1922–1996). His book *The Structure of Scientific Revolutions* outlines how these revolutions come about, the possible paths that they follow, who are the people most likely to initiate them, and their importance for scholarly progress.

Kuhn argues that revolutions may come from two main sources: (1) a major breakthrough or empirical finding or (2) a new line of thought that gains momentum and is incompatible with previously accepted conceptualizations. In this sense, a scientific revolution brings about theoretical reformulations and a necessary reassessment of previously established truths. For Kuhn, theoretical and epistemological constructs have an orienting role that shapes not only the kinds of explanations researchers arrive at when considering a phenomenon but also the very questions they ask and the observations they conduct. He describes a *paradigm* as a broadly influential framework that shapes more specific research programs and theoretical constructs, within and across various disciplines. When accepted paradigms begin to lose their explanatory power, the opportunity arises for the emergence of new ones that will eventually replace them, leading to a shift in perspective. The concept of paradigm is connected to that of *disciplinary matrix*, which encompasses both the problems and the investigative practices that are normatively addressed within a discipline.

Kuhn proposes that revolutions may evolve in different ways: For example, radically new ideas may be marginalized for a while or quickly brought to center stage, openly debated, and tested. They may spark deep disagreement between different members of a scholarly community, or they may be embraced by influential individuals who help validate and promote them. Interestingly, the people most likely to come up with a revolutionary idea are often those who are not already situated high in the ranks of academic power: They may be very young or not fully schooled in the established ways of a particular discipline. Because they have not yet endorsed existing paradigms, these individuals are able to bring a fresh perspective to old problems.

Scientific revolutions often take place over a period of time, and they can occur in all disciplines. They always create some degree of conflict and uncertainty, as the shift from an established set of conceptualizations and expectations to a newer one moves through a period of transition and redefinition. Nevertheless, once the new ideas become broadly accepted, they are incorporated into the established ways of thinking and doing of the scholarly community, therefore losing their revolutionary character. So, the larger cycle begins again, as any established conceptualization is likely to be eventually challenged by new research or new theoretical constructs.

Another prominent philosopher of science, who influenced Kuhn's ideas on theory development, is Karl Popper (1902–1994). One of the contributions made by Popper involves his exploration of the characteristics that define a scientific theory as such, separating it from pseudoscientific or folk knowledge. In his book *Conjectures and Refutations*, Popper discusses the main ways that theory developments occur, bringing along with them scientific or conceptual revolutions. Popper argues that theories can be either supported or disproven, so research that attempts to test an existing theory leads to either a confirmation of its basic propositions or a refutation that forces its reassessment. However, many theories are so big, abstract, and complex that they can hardly be *proven* in definitive terms as positive explanations of phenomena; yet as long as they cannot be *proved wrong*—or falsified, as he says—they continue to stand as plausible explanations. Particular

aspects of them may be tested, and the evidence may either support the theory's propositions or not, thus forcing an examination of the whole that can lead to new ideas. While discussing this, Popper engages with issues of epistemology, also considering topics such as validity and normalization within scholarly debates—which are also connected to theory change.

Overall, scientific revolutions, insofar as they represent a paradigm shift and the emergence of new disciplinary matrices, may have an impact that stretches across a variety of fields. Because this may include the humanities and other areas not considered strictly *scientific*, authors such as Paul Thagard have proposed a broader term: *conceptual revolutions*, which designates a profound shift in perspective that has theoretical and practical implications. Revolutions facilitate the introduction of new theoretical constructs, which may compete for acceptance with preexisting theories. Some fields may be less likely to tolerate competing conceptualizations without allowing for the emergence of a dominant framework. However, in other fields, a variety of theories may coexist as alternative explanations for the same phenomena, leading to parallel conceptual definitions and research agendas.

Historical Changes and Epistemological Shifts During the Renaissance

Popper proposes that a theory can be seen as a tool or lens that scholars use in order to explain and understand what happens in the world—and this tool or lens is the product of its time and place. Theories may be proposed by individual authors, but it is their broad acceptance by an academic community that determines the extent of their influence within a scholarly field. Regardless of attempts to establish science as an objective and neutral realm, research is inscribed within historical contexts. The scientific revolution was the result of profound intellectual changes that took place in Europe during the 16th, 17th, and 18th centuries. This period enabled the development of all the natural and social sciences and influenced a number of social, economic, and political transformations that later shaped the modern world. For example, the rise of urbanism

and industrialization, the founding of multiple institutions of higher education, and the allocation of state funds to support scientific pursuits accompanied the emergence of new health programs, technological advancements, and bureaucratic processes.

The conceptual shifts that shaped the scientific revolution in Europe emerged during the period that spans from the Renaissance to the Enlightenment. During the preceding period, the Middle Ages, dominant views of nature, humanity, and life were shaped by the principles of the Catholic faith, so the goal of all studies was to discover truths that honored God and his creation. This implied a particular epistemological framework that also limited the kinds of phenomena deemed suitable for inquiry: The pursuit of other kinds of knowledge (e.g., about the biological structure of the human body) was strongly discouraged, and propositions that challenged the established order were harshly sanctioned. Institutions such as the Inquisition exercised a disciplining role in numerous territories. Nonetheless, the advent of the Renaissance brought along a radical reformulation of dominant ideas regarding nature, society, humanity, and knowledge, both within intellectual circles and larger communities. Many of these ideas were underpinned by a shift of emphasis from the divine to the natural world, reigniting an engagement with worldly issues, as religious matters lost their privileged position and were replaced by an interest in emergent political movements. This shift in perspective brought along a reassessment of humankind's place within the natural order and yielded new conceptual frameworks throughout the sciences.

The Renaissance began in what is now Italy and involved a rediscovery of writings by classical philosophers, poets, astronomers, and mathematicians of classical antiquity. Some of them—such as Plato and Aristotle—were already studied at the time, and their ideas were incorporated into canonical scholarly works. However, many others had been largely ignored since the fall of the Western Roman Empire in the 5th century C.E., even as numerous manuscripts were preserved in the libraries of the Eastern part of the empire, also known as *Byzantium*. After the fall of Byzantium in the 15th century, several factors facilitated a large conceptual shift among learned communities

in Europe: Classical works were rediscovered, inventions such as the printing press made books available to a wider population, and observations conducted by scholars such as Nicolas Copernicus and Galileo Galilei challenged the dogmatic ideas that had prevailed until then. The establishment of the first universities, starting in the 11th and 12th centuries, had helped formalize areas of study such as theology, philosophy, medicine, and the law, and the expansion of educational institutions in the centuries that followed shaped the ensuing intellectual debates, creating spaces for new theoretical understandings.

The beginning of the Renaissance was marked by major political crises and significant social changes. Former feudal kingdoms merged and gave rise to new nation-states that claimed specific territories and soon initiated projects of conquest and expansion. Challenges to medieval ways of life and modes of thought included a critique of the serfdom-based loyalties that supported feudal institutions and a reshaping of the social structure in order to accommodate an emerging class of traders and bankers. As Christopher Columbus and other adventurers traveled to the New World, evidence of new geographical territories forced a reassessment of old cartographic knowledge and a redrawing of maps. The perceived mystery of the Americas soon heralded a new era of exploration and colonization that brought both tangible and conceptual novelties to the European continent. The conquest effort, marked by violence, would lead to centuries of clashes with indigenous communities and the enslavement and domination of specific groups of people, which further shaped social and political affairs around the world. Meanwhile, the religious reformation that began in Europe in the 16th century and led to the emergence of Protestantism sparked a wave of religious conflict, bringing about several lengthy and violent wars that changed the landscape of the continent.

In the midst of all this, a profound change in perspective took place within scholarly communities, enabling paths of inquiry that were not previously available. Renaissance scholarship encouraged an active engagement with multiple arts and sciences and promoted curiosity and experimentation. Two of the most iconic figures of the Renaissance are Leonardo Da Vinci and

Erasmus of Rotterdam, both active in the 15th and 16th centuries. Leonardo's interests and extraordinary skills ranged from the arts to engineering, botany, and writing, and he was among the first to venture into investigating previously forbidden matters such as the inner workings of the human body, producing anatomical drawings that were used in the study of medicine. Erasmus of Rotterdam, a Dutch humanist and scholar, revolutionized philosophy by placing humanity at the center of his inquiry, instead of divine and spiritual affairs. In broader terms, Renaissance thought questioned generally held assumptions regarding humanity, nature, good, evil, and God, bringing along the possibility of engaging with many new topics. The changes that occurred during this period had far-reaching consequences from the point of view of epistemology and theorization, and established the foundation for the emergence of new disciplines and new scholarly practices.

The Scientific Revolution and the Scientific Method

The Scientific Revolution brought along a way of thinking that disregarded folk wisdom as a source of knowledge, putting emphasis on direct observation and evidence in order to draw general conclusions. It encouraged a detailed recording of the logical steps followed during the inquiry process and facilitated the accumulation and dissemination of knowledge through written treatises and manuals. This marked an epistemological and methodological shift with regard to the practices that were used previously, when explanations of natural or historical events were often codified in myths and folklore that were transmitted through oral or literary traditions. The emphasis on direct observation and measurement also challenged the abstract philosophical deductions used in many scholarly pursuits, such as Aristotelian syllogisms.

One of the best examples of a paradigm change that shook widely held assumptions and had an influence across the disciplines during the time of the Scientific Revolution was heliocentrism, which was first proposed by Nicolas Copernicus and later defended by Galileo Galilei. An Earth-centered conceptualization of the planetary system

had prevailed for more than a thousand years, so the idea of a solar system in which the planets circled around the sun was groundbreaking. This had implications not just for the way people studied the cosmos but also for the way they thought about their own place in the universe; furthermore, because the new model challenged the perceived order of things, it was deemed politically dangerous. When Copernicus's work was published in 1543, it was controversial. The evidence later gathered by Galileo, a 17th century mathematician, raised the matter's profile even more, and the Inquisition stepped in to suppress it. It was only after Galileo's death that the accuracy of his observations was determined, leading to a paradigm shift that opened new pathways for inquiry into the workings of the universe.

The Scientific Revolution led to the establishment of a range of new disciplines, including biology, chemistry, and engineering. Significantly, it produced a particular protocol for conducting research—the *scientific method*—which continues to be used today. The method provides a step-by-step procedure that scholars can follow in order to arrive at valid results, and its guiding principles are objectivity, controlled manipulation of variables, and conceptual separation between the observer and the observed. The purpose of research conducted with the scientific method is usually to predict future outcomes and accrue knowledge that can potentially have practical applications and solve specific problems. Moreover, the scientific method establishes normative guidelines for conducting and evaluating research in a manner that is systematic and organized. The basic steps of the method are four: question, hypothesis, test, and analysis. Thus, the process begins with a preliminary observation of phenomena and the drafting of research questions. This is followed by a review of relevant literature and the formulation of one or more plausible hypotheses. The next steps, test and analysis, involve designing an experiment or conducting systematic observations in order to collect empirical proofs. Testing is ideally conducted within a controlled environment, which requires isolating and manipulating variables so as to observe specific outcomes. The analysis of the results is to be done objectively, with the help of inferential statistics and mathematical formulas, so this kind of scholarly work is

also called *quantitative research*. Finally, the goal of the analysis is not just to observe general trends but to discover statistically significant relationships that can be affected by induced manipulations and are unlikely to occur by chance.

The scientific method is connected to a particular epistemological stance: namely the idea that the workings of the world can be objectively uncovered through direct observation and measurement and that future outcomes can be predicted on the basis of recorded data. The protocols that accompany the scientific method also establish specific processes for the development, refutation, or proving of new theories, which are supposed to arise in connection with a research question and must represent an effort to account for accrued evidence. Insofar as any research project that uses the scientific method is based on a review of literature and new findings can lead to new research projects, the scientific method points to a steady accumulation of knowledge. Furthermore, the results of research done with the scientific method are expected to be consistent and replicable—meaning that similarly conducted observations should yield similar findings—which shapes how new discoveries are handled by scientific communities. Because of all this, the scientific method establishes a particular way of examining the world and producing knowledge. Today, the method is used in all the biological and physical sciences, as well as many of the social sciences.

Philosophy of Science, Rationalism, and Enlightenment

In the 18th and 19th centuries, thinkers such as Immanuel Kant (1724–1804) and G.W. F. Hegel (1770–1831) strived to articulate a *philosophy of science* that would engage with debates on ethics, reasoning, and human experience, while also considering humanity's place within the natural world. Kant's *Critique of Pure Reason* focuses on issues of epistemology and validity in logical inquiry, while Hegel's writings emphasize the importance of systematic analysis and advance a teleological view of history that greatly influenced later writings on dialectics and materialism. The emphasis on reason that appears in the work of both philosophers is connected to the rise of an intellectual current that shaped epistemological and

theoretical debates within scientific fields: rationalism. Both Hegel's ideas regarding the primacy of "pure Thought" and René Descartes's (1596–1650) often-quoted maxim "I think, therefore I am" constitute examples of rationalist philosophy.

The rationalist view of humans as intellectual beings who could dominate and rule a mindless natural world was far removed from medieval conceptualizations of humanity and nature that were centered on the acceptance of a divine order. Rationalism conceived the human intellect as the primary force of history, validating attempts to manipulate the natural world by means of technology and industry. In tune with the perspectives that reigned during the Scientific Revolution, rationalism valued logical reasoning, a careful collection of data, systematic analysis, and detailed record-keeping, in order to arrive at a conclusion, truth, or prediction. Its proponents often engaged with political and economic issues of their time, approaching problems with a mindset that focused on the maximization of resources. This epistemological approach was eminently represented in the ideas of authors such as John Locke (1632–1704), Francis Bacon (1561–1626), and Isaac Newton (1643–1727), whose work would range from propositions regarding government to advancements in engineering.

The intellectual landscape of Europe during the Scientific Revolution also enabled the development of a line of thought that later gave form to a political and social project: the Enlightenment. Enlightenment ideals embraced the principles of rationalism, but proponents added a specific concern with progress and strived toward the betterment of the human condition, paying particular attention to such aspects as education and economic development. Their connection to science resided in the belief that technological and scientific advancements would provide the means for solving all kinds of problems—a belief that was underscored by an optimistic view of human nature and societal progress. Enlightenment thought engaged with revolutionary ideas such as universal education, industrialization, market economics, social reform, and representative democracy, giving rise to new theories of government, society, and human behavior. Within the political sphere, the epistemology of the Enlightenment

shaped projects that influenced historical events such as the French Revolution and the emancipation of the American colonies. Some of its major proponents were Voltaire, Montesquieu, Jean-Jacques Rousseau, David Hume, and Adam Smith, whose ideas influenced generations of scholars.

Enlightenment thought provided the backdrop and the fuel for the extraordinary growth that the sciences experienced during the 19th century and the beginning of the 20th century. At that time, radically new conceptual propositions—such as Charles Darwin's *theory of evolution* and Albert Einstein's *theory of relativity*—were developed, which led to theoretical reformulations and a wealth of empirical research in various fields. Although some aspects of the Enlightenment project were later critiqued, many of its fundamental principles continue to hold appeal, especially regarding the relationship between reason and research, political and social progress, and science and development.

20th-Century Conceptual Revolutions

The 20th century saw both an extraordinary growth in the theoretical base of the natural and social sciences, and the emergence of a critique of the principles orienting research and theorization since the Scientific Revolution. The Enlightenment's trust in the promise of science and technology as a means for solving human problems contributed to the prominent place that the sciences were given within the scholarly community throughout the 19th and 20th centuries. Breakthroughs in health care, such as the discovery of vaccines and antibiotics, and new developments in transportation, telecommunications, and space exploration gave credence to the belief that applied science could hold the answers to many issues, directly impacting people's quality of life in modern societies.

The epistemological perspective that defined much of the scholarly work done during those two centuries was empirically oriented. Empirical research used the scientific method and embraced the premise that the world is objective, the answers to any questions about the world can be found by well-crafted research designs, and good science is neutral in terms of its processes and consequences. Empirical approaches were

dominant within the research carried out within new disciplines such as psychology and sociology, in addition to the hard sciences, and shaped the theoretical constructs that emerged from those fields. For example, *behaviorism*—a theoretical framework that used empirical and positivistic methods to investigate living organisms—was proposed by the psychologist B. F. Skinner (1904–1990) and emphasized observable behavior and cause-and-effect reactions, becoming influential within various disciplines, including psychology and education.

World affairs that defined the 20th century also impacted scholarly communities and led to new conceptual formulation. For example, the two world wars reshaped the political map of Europe and global power dynamics; increased urbanization and industrialization changed the character of city life and the nature of labor; and technological innovation changed the way information was produced and disseminated throughout the world. This was accompanied by significant socioeconomic and cultural shifts that also became the topic of academic debate. On a different level, scholarly practices were further shaped by factors such as the creation of many new public universities, the introduction of corporate funding into some research arenas, and the creation of worldwide academic networks and professional associations.

In an effort to develop epistemological and theoretical tools to understand the social and political transformations going on at the time, new approaches to research were developed, some of which constituted conceptual revolutions in their own right. Critics of empirical research argued that the framework had limited explanatory power for problems involving naturalistic and highly complex social environments, where observable variables and measurements could not account for multiple and simultaneous interconnections. Hence, during the second half of the 20th century, two emergent epistemological and conceptual frameworks had a significant impact across many fields: *cognitivism* and *critical theory*. They both challenged assumptions derived from rationalism and the Enlightenment, and they both were foundational for the development of new disciplines within the academy.

An interest in the workings of the human mind greatly increased throughout the 20th century—science had made enormous progress in its exploration of the natural world, but the human brain remained largely a mystery. The introduction of *psychoanalysis* as a theoretical framework had shaken many social norms, with Sigmund Freud's propositions regarding the unconscious, the ego, and innate sexual drives impacting various intellectual circles and artistic movements. Yet the core ideas of psychoanalysis could hardly be proven through empirical means. Partly aided by the development of new surgical instruments and new devices that could be used to obtain glimpses into the workings of the brain and therefore of the mind, research on the brain and brain disorders showed a marked growth around the 1970s. With it, a new conceptual framework emerged: *cognitive theory*. Whereas psychoanalysis had focused on subconscious drives and the effects of traumatic experiences, and behaviorism had bracketed the *black box* of the mind in order to focus on observable behavior, cognitivism sought to discover the internal logic and the hidden structures of the mind, as well as of human faculties such as thought, memory, and language. Hence, it sought to make sense of both the biological and social aspects that influenced people's thoughts and behaviors.

The epistemological framework that cognitivism brought forth deeply impacted disciplines such as psychology and linguistics, which experienced a cognitive turn that modified not only the problems tackled by standard research projects but also their methods and their goals. For example, linguistic analysis had been carried out for years on the basis of comparative, anthropological, or philological approaches, but cognitivism brought along new questions regarding the structure of language and the mind, which were revolutionary. New thinkers such as Noam Chomsky (1928–) and Steven Pinker (1954–) developed propositions regarding generative linguistics, linguistic universals, and language development. Impacting a number of other disciplines, the cognitive revolution brought with it a direct engagement with questions regarding the connection between the mind, the brain, and the world, stirring up epistemological debates within the humanities and social sciences.

Meanwhile, the social and political changes that occurred in the 20th century led other thinkers to develop a theoretical and methodological framework that directly challenged the principles of the scientific method: *critical theory*. The Nazi regime, the establishment of the Union of Soviet Socialist Republics, the Civil Rights movement, the feminist movement, and other historical events and cultural transformations prompted a scrutiny of the principles underlying the frameworks of analysis that had been in use since the Enlightenment. Critical scholars dismissed the idea that research should be neutral, objective, and separated from political affairs, instead seeking to directly engage with topics such as ideology, power, and inequality in contemporary society. Their goals were to scrutinize structures of domination and contribute to social change, while empowering and reasserting the validity of marginalized voices and experiences. In this sense, critical theory posed an epistemological shift that would yield new methods of analysis, later grouped under the umbrella of *qualitative research*. Because of this, its introduction in academe was revolutionary.

Critical theory developed in connection to a critique of the status quo and a desire to support social transformation. Early landmarks in the formulation of its principles included the publication and dissemination of Karl Marx's *Capital*, which presented a comprehensive critique of capitalism as a system that structures not just economic relations but also social and political formations. The arguments put forth by Marx were taken up by many later authors, and the influence of Marxism went well beyond intellectual circles, leading to the creation of revolutionary political movements. Within the academy, critical theory was enriched in the 1940s and 1950s by the work of scholars who came to be collectively named the *Frankfurt School*—a group that included Walter Benjamin, Theodor Adorno, Max Horkheimer, Herbert Marcuse, and later, Jürgen Habermas. Horkheimer, Adorno, and Marcuse were among the many intellectuals and artists who emigrated to the United States to escape from Nazi Germany. Their writings were influenced by European philosophers such as Hegel, and their analysis of contemporary U.S. American society was foundational for the

emergent theoretical framework. Adorno, for example, was critical of the goals of empirical research and the role that scientific pursuits had in America, where they apparently served the interests of large corporations and the State. He was also concerned with ethical matters, such as the way scientific pursuits could be linked to abuse in the name of a higher good.

In the 1960s and 1970s, as social movements for civil rights, peace, feminism, and gender equality gained prominence, intellectuals who belonged to groups that had been historically marginalized from scholarly communities began to challenge the emancipatory promises of modern science. They argued that science tended to either obliterate or objectify the experience of women and people of color, while masking a myriad of biases under a cloak of neutrality. Furthermore, they stated that theory and research are never objective because dominant ideologies percolate conceptual constructs and methodological protocols. For example, Michel Foucault (1926–1984), author of *The Archaeology of Knowledge*, explains that conceptual revolutions go hand in hand with larger social changes, advocating for a rethinking of contemporary social institutions, which stand in connection to discursive practices and ideological formations.

Critical scholarship influenced the development of other theoretical frameworks, such as cultural studies, which originally developed in England in the 1960s and directly supported interdisciplinary conversations. Cultural studies scholars also rejected quantitative research, arguing that it reduced social phenomena to measurable bits, and instead embraced *grand theory* because they believed it offered better possibilities for explaining the historical complexity of social realities. This led to the development of new objects of research, such as media, and new methods of qualitative inquiry. Qualitative methodologies such as ethnography, text analysis, and structured interviews gained an increased validity during the 1980s and 1990s, and today, they are widely used—their introduction prompted a conceptual revolution insofar it led to a deep reformulation of the standards that were associated with scholarly research. Besides entering fields such as sociology, communication, literature, and political science, critical and cultural theory greatly influenced

the epistemological perspectives used in new disciplines such as Women's and Gender Studies and Ethnic Studies.

In sum, scientific or conceptual revolutions can be brought along by new discoveries or novel reformulations of existing ideas, which force a scrutiny of the standard theoretical perspectives and research methods used within a given discipline. Significant advancements in science and technology may bring about a specific scientific revolution, as they have done throughout history, but in broader terms, a revolution that reshapes the conceptual base of a scholarly field can take place in any discipline and in any period of time. Often, new and revolutionary perspectives do not emerge from the higher ranks of an established field but come from the margins or from neighboring areas of study. Conceptual revolutions may be sparked by major discoveries or unanticipated findings that force a revision of existing theories or by forceful arguments that shed new light on old assumptions. Epistemological and philosophical inquiries regarding the nature of knowledge have significantly influenced scientific and scholarly pursuits during the last centuries—and have been influenced by them as well. The history of the modern world has been shaped by developments in science, and many contemporary standards regarding scholarly research refer back to the protocols developed during the Scientific Revolution. Within the academy, newer conceptual revolutions have brought along new research methodologies and defined new objects of study, which have impacted the scholarly work done across many disciplines.

SEMANTICS (INTRODUCTION TO THEORY)

Semantics is the part of linguistics that is concerned with meaning. Meaning is a notion with a wide range of applications, some of which belong to the field of semantics while others lie beyond it. Meaning is always the meaning of something. Words have meanings, as do phrases and sentences. Semantics is exclusively concerned with the meanings of linguistic entities such as words, phrases, grammatical forms, and sentences, but not with the meanings of actions or phenomena. The meanings of words and sentences cannot be studied independently of how they are actually

used in speech. After all, it is language use that provides the data for semantics. Therefore, the meanings of linguistic utterances also matter to semantics.

The technical term for using an expression for something is *reference*. The function of the pronoun *I* is reference to the speaker of the sentence: When people use *I*, they refer to themselves. The entity referred to by an expression is called its *referent*. So the *referent* of *I* is always the speaker. The meaning of the pronoun can thus be described as follows: *I* indicates reference to the speaker. Similarly, the pronoun *you* indicates reference to one or more addressees.

This entry describes and explains the various forms of meaning addressed within the domain of semantics and concludes with some general observations about the relationship between the study of semantics and the modern approach to linguistics.

Expression Meaning and Utterance Meaning: Truth Condition

The meanings of words, phrases, and sentences, taken as such in their general sense, apart from any particular context, constitute the level of meaning which will henceforth be called *expression meaning*. *Expression* is just a general term for words, phrases, and sentences. The term *expression meaning* covers, in particular, word meaning and sentence meaning. The level of *expression meaning* constitutes the central subject of linguistic semantics. It studies the material, or equipment, as it were, that languages provide for communication.

In addition to *expression meaning*, there is *utterance meaning*. It comes about when a sentence with its meaning is actually used in a concrete context. First of all, *utterance meaning* involves *reference*. In addition to, and in connection with, reference another central notion comes into play, the notion of *truth*. The question of *truth* primarily concerns declarative sentences. Only such sentences, when uttered, are true or false. But it matters also for interrogative and other types of sentences. For example, if John asked Mary *Do you need my bicycle?*, the use of the question form would convey that he wants to know from his addressee whether, from her perspective, *I need your bicycle* is true or false.

In the literature of semantics, the notion of utterance meaning is not used in a uniform way. The technical term for this is *context of utterance*. Roughly speaking, the context of utterance is the sum of circumstances that bear on reference and truth. The most important ones are the following aspects: (a) the speaker (or producer) of the utterance, (b) the addressees (or recipients) of the utterance, (c) the time at which the utterance is produced and/or received, (d) the place where the utterance is produced and/or received, and e) the facts given when the utterance is produced and/or received.

In certain cases, such as communication by mail, the time, place, and facts may differ for the production of an utterance and its reception. Given this background utterance, meaning can be defined as the meaning that results from using an expression in a given communicative utterance. Utterance meaning derives from expression meaning on the basis of the particulars provided by the communicative utterance. The only aspects of the communicative utterance that matter are those that immediately bear on reference and truth of the expression.

Making Inferences

When someone produces an utterance, the addressees usually make various kinds of inferences. Although these inferences are somehow triggered in the addressee's mind, it is important to separate what is actually being said from what is inferred. Some authors prefer not to draw this distinction and adopt a very wide notion of utterance meaning. The investigation of such inferences, their role in communication and how they are related to the meaning, of what is actually said, is an important part of the linguistic discipline called *pragmatics*, the scientific study of, roughly speaking, the rules that govern language use. Within pragmatics, Paul Grice's theory of conversational implicatures deals with inferences of this kind.

Utterance meaning is also of concern for semantics: It has to explain how reference and truth depend on the context of utterance. For example, a semantic theory of tense would have to describe and explain which relations to the time of utterance present, past, and future tense forms can indicate. A further important subject, gradually gaining

importance, is the analysis of the systematic meaning shifts that expression meanings may undergo.

Communicative Meaning

Neither the level of expression meaning nor that of utterance meaning is the primary level on which we interpret verbal utterances. In an actual exchange, the main concern inevitably is this: What does the speaker intend with the utterance; in particular, what does the speaker want from me? Conversely, when we take on the speaking part, we choose our words in pursuit of a certain communicative intention. Verbal exchanges are a form of social interaction. They form an important part of our social lives. As such, they will always be interpreted as part of the whole social exchange and relationship entertained with the speaker.

A theory that addresses this level of interpretation is speech act theory, introduced in the 1950s by the philosopher John L. Austin and developed further by others, in particular John R. Searle. The central idea of speech act theory is that whenever we make an utterance in a verbal exchange we act on several levels. One level is what Austin calls the *locutionary act*. A locutionary act is the act of using a certain expression (usually a sentence) with a certain meaning in the given context of utterance. In doing so, we also perform an illocutionary act on the level on which the utterance constitutes a certain type of *speech act*: a statement, a question, a request, a promise, a refusal, a confirmation, a warning, and so forth.

The speech act level will be referred to as *communicative meaning*. Unlike expression meaning and utterance meaning, communicative meaning lies outside the range of semantics. Rather, it is of central concern for pragmatics.

Therefore, a more precise and comprehensive definition of semantics would be the following. Semantics is the study of the meanings of linguistic expressions, either simple or complex, taken in isolation. It further accounts for the way utterance meaning—that is, the meaning of an expression used in a concrete context of utterance—is related to expression meaning.

To summarize the levels of meaning, the following definitions can be surmised: (a) Expression meaning is the meaning of a simple or complex

expression taken in isolation; (b) utterance meaning is the meaning of an expression when used in a given context of utterance with fixed reference and truth value (for declarative sentences); and (c) communicative meaning is the meaning of an utterance as a communicative act in a given social setting. Hence, three levels of meaning are identified and defined.

Sentence Meaning and Compositionality

Although we usually understand sentences without any conscious effort, their meanings must be derived from our stored linguistic knowledge. This process is technically called *composition*. Complex expressions whose meanings are not stored in the lexicon are therefore said to have *compositional meaning*.

The meaning of complex expressions is determined by semantic composition. This mechanism draws on three sources: (a) the lexical meanings of the basic expressions; (b) the grammatical forms of the basic expressions; and (c) the syntactic structure of the complex expression. Thus, the principle of compositionality states that the meaning of a complex expression is determined by the lexical meanings of its components, their grammatical meanings, and the syntactic structure of the whole. The principle implies that the meanings of complex expressions are fully determined by the three sources mentioned—that is, by the linguistic input alone. Thus, in particular, the process does not draw on extralinguistic context knowledge. The principle as it stands can therefore be taken as an indirect definition of expression meaning, since expression meaning is that level of meaning that can be obtained by the process of composition—that is, on the basis of lexical meanings, interpretation rules for grammatical forms, and semantic combination rules.

It should be noted that the principle does not hold for the level of utterance meaning. Utterance meaning can only be determined by bringing in nonlinguistic knowledge about the given context of utterance.

Therefore, the principle of compositionality yields a convenient division of semantics into the following subdisciplines: *lexical semantics*, which is the investigation of expression meanings stored in the mental lexicon; *compositional word*

semantics, which is the investigation of the meanings of words that are formed by the rules of word formation; *semantics of grammatical forms*, which is the investigation of the meaning contribution of grammatical forms that can be freely chosen, often understood as including the semantic analysis of function words such as articles, prepositions and conjunctions; and *sentence semantics*, which is the investigation of the rules that determine how the meanings of the components of a complex expression interact and combine. Often semantics is subdivided into two subdisciplines only: Lexical semantics is then understood as also comprising compositional word semantics, and the semantics of grammatical forms is subsumed under sentence semantics.

Meanings as Concepts

The meaning is a mental description. For mental descriptions in general the term *concept* can be used. A concept for a kind, or category, of entities is information in the mind that allows us to discriminate entities of that kind from entities of other kinds. However, a concept should not be equated with a visual image. Many categories we have words for such as *mistake*, *thought*, *noise*, *structure*, and *mood* are not categories of visible things. But even for categories of visible things such as *dogs*, the mental description is by no means exhausted by a specification of their visual appearance. The *dog* concept, for instance, also specifies the behavior of dogs and how dogs may matter for us as pets, guide dogs, and so on.

The ideas and statements about the meanings of words and sentences can be presented as follows. The meaning of a word, more precisely, a content word (noun, verb, and adjective), is a concept that provides a mental description of a certain kind of entity. The meaning of a sentence is a concept that provides a mental description of a certain kind of situation.

Descriptive Meaning of Sentences: Propositions

The descriptive meaning of a sentence, its proposition, is a concept that provides a mental description of the kind of situations it potentially refers to. It is not only content words that shape the descriptive meaning of

the sentence. Functional elements, such as pronouns and articles or tense, a grammatical form, contribute to the proposition as well. Thus, the descriptive meaning of a word or a grammatical form is its contribution to descriptive sentence meaning.

Denotations and Truth Conditions: Semiotic Triangle

The denotation of a content word is the category, or set, of all its potential referents. The denotation of a word is more than the set of all existing entities of that kind. It includes real referents as well as fictitious ones, usual exemplars and unusual ones, maybe even exemplars we cannot imagine because they are yet to be invented.

The relationship between a word, its meaning, and its denotation is often depicted in the semiotic triangle, a convenient schema that is often used by linguists.

There is no established term for what would be the denotation of a sentence. By analogy with the denotation of a content word it would be the set, or category, of all situations to which the sentence can potentially refer; that is, the category of all situations in which the sentence is true. There is, however, another notion that is quite common and directly related to the would-be denotation of a sentence: Its so-called truth conditions. The truth conditions of a sentence are the conditions under which it is true. If we know the truth conditions of a sentence, then we know which situations the sentence can refer to; that is, the denotation of the sentence. Conversely, if we know which situations a sentence can refer to, we know its truth conditions. Thus, the notion of truth conditions can be considered the practical equivalent of the notion of the denotation of a sentence. The descriptive meaning of the sentence is its proposition, and the proposition determines the truth conditions of the sentence.

It should be also noted that the grammatical type of a sentence contributes its meaning, and this contribution is nondescriptive. For instance, the two propositions can be compared: (a) *The rain has ruined our trip*; (b) *Has the rain ruined our trip?* In this set of sentences, the question describes exactly the same sort of situation. Hence, it is considered to have the same proposition as the declarative sentence. The difference in

meaning is due to the grammatical forms of the sentences, or more precisely, to differences in grammatical sentence type. The semantic contribution of the grammatical sentence type is not part of the proposition. For declarative sentences, it consists in presenting the situation expressed as actually pertaining. This sentence type is therefore used for making assertions and communicating information. The interrogative sentence type, by contrast, leaves open whether or not the situation pertains. It is therefore the standard option to be chosen for asking questions. Thus, the meaning contribution of grammatical sentence type is non-descriptive meaning.

Linguistic Approach to Semantics

The key element of the modern linguistic approach to semantics is that there is no escape from language. The goal of semantics is to study relations within language such as paraphrase or synonymy, paraphrase or antonymy, and so forth. Another task of semantics is seeing language study as the explication of the linguistic competence of the native speaker of a language, or in other words the provision of rules and structures which specify the mental apparatus a person must possess if he is to know a given language. For the linguist, the main difficulty lies in drawing a boundary not simply between sense and nonsense but between the kind of nonsense that arises from contradicting what we know about language and meaning, and the kind of nonsense that comes from contradicting what we know about the real world.

SEMANTICS (SCIENTIFIC AND EMPIRICAL)

Semantics is the aspect of the discipline of linguistics that is concerned with meaning. This entry discusses some of the more technical aspects of

semantics. For a general introduction, please see the entry Semantics (Introduction to Theory) in this encyclopedia.

The sections that follow present the fundamentals of key topics in semantics, including lexemes, homonyms, polysemy, and semantic ambiguity. Next, expressive meaning and the importance of cognitive psychology for semantics are discussed, and the entry concludes with some observations on the relationship between meaning and cognition.

Lexemes and Lexicon of a Language

Lexemes are focal elements of modern semantic analysis, both scientific and empirical. Expressions with a lexical meaning are referred to as *lexemes* or *lexical items*. Lexemes constitute the lexicon of the language, a huge complex structure in the minds of the language users. Lexical meanings we have in our mental lexicons are not just paraphrases. They are concepts.

Lexemes differ in their grammatical behavior and are accordingly assigned to different grammatical categories such as verbs, nouns, and adjectives. Occasionally the term *word class* is used instead of grammatical category. The grammatical category determines the way in which a lexeme can be used within a sentence. For example, a noun can be combined with an adjective, and the whole with an article to form a noun phrase. The noun phrase in turn can be combined as object with a verb to form a verb phrase, and so forth.

Thus, a lexeme is a linguistic item defined by the following specifications, which make up what is called the *lexical entry* for this item: (a) its sound form and its spelling (for languages with a written standard); (b) the grammatical category of the lexeme (noun, intransitive verb, adjective, etc.); (c) its inherent grammatical properties (for some languages, e.g., gender); (d) the set of grammatical forms it may take, in particular irregular forms; and (e) its lexical meaning. These specifications apply both to simple and composite lexemes. Composite lexemes too, such as *throw in the towel* or *red light*, have a fixed sound form, spelling, and lexical meaning. They belong to a grammatical category (intransitive verb for *throw in the towel* and noun for *red light*), they have inherent grammatical properties and the usual range of grammatical forms. For example, the grammatical

forms of *throw in the towel* are those obtained by inserting the grammatical forms of the verb *throw*: *throws in the towel*, *threw in the towel*, and so on.

In principle, each of the specifications of a lexeme is essential: If two linguistic items differ in one of these points, they are considered different lexemes. There are, however, exceptions. Some lexemes have orthographic variants, for example, *rhyme/rime*, others may have different sound forms, for example, *laboratory* may be stressed on either the first or the second syllable. The American and the British variants of English differ in spelling and sound form for many lexemes. As long as all the other properties of two orthographic or phonetic variants of a lexeme are identical, in particular their meanings, they will not be considered different lexemes but lexemes with a certain limited degree of variation. That does not mean that minor differences do not count. They count in any event if they are connected with a difference in meaning.

Homonymy, Polysemy, and Vagueness

Homonymy

Words with the same historical origin are called *cognates*. *Light* is a cognate of a different German word, the adjective *leicht* (light, easy). Due to their different origins, these two units are considered two different lexemes by most linguists. In general, different meanings are assigned to different lexemes if they have different historical sources. The idea is that as long as their meanings remain distinct, different words do not develop into one, even if their sound forms and/or spellings happen to coincide for independent reasons. The two adjectives *light* and *leicht* are an instance of what is called *total homonymy*: two lexemes that share all distinctive properties (grammatical category and grammatical properties, the set of grammatical forms, sound form, and spelling), yet have unrelated different meanings. One would talk of partial homonymy if two lexemes with different unrelated meanings coincide in some but not all of their grammatical forms, for instance, the verbs *lie* (*lay*, *lain*) and *lie* (*lied*, *lied*). Partial homonyms can give rise to ambiguity in some contexts (do not lie in bed) but can be distinguished in others (*he lay/lied in bed*).

Homonymy can be related either to the sound forms of the lexemes or to their spellings: Homonymy with respect to the written form is *homography*; if two lexemes with unrelated meanings have the same sound form, they constitute a case of *homophony*.

Polysemy

A lexeme constitutes a case of polysemy if it has two or more interrelated meanings, or better: meaning variants. The phenomenon of polysemy is independent of homonymy: of two homonyms, each can be polysemous. It results from a natural economic tendency of language. Rather than inventing new expressions for new objects, activities, experiences, and so forth to be denoted, language communities usually opt for applying existing terms to new objects, terms hitherto used for similar things. Scientific terminology is one source contributing to polysemy on a greater scale. Some scientific terms are newly coined, but most of them will be derived from ordinary language use. Among the terms introduced in semantics, *lexeme*, *homonymy*, and *polysemy* are original scientific terms, while others, such as *meaning*, *reference*, and *composition*, are ordinary expressions for which an additional technical meaning variant was introduced. In principle, polysemy is a matter of single lexemes in single languages. Polysemy plays a major role in the historical development of word meanings because lexemes continually shift their meanings and develop new variants.

Semantic Ambiguity or Vagueness

Many words have more than one meaning, and even complete sentences may allow for several readings. The term for this phenomenon is *ambiguity* (or *vagueness*): An expression or an utterance is ambiguous if it can be interpreted in more than one way. The notion of ambiguity can be applied to all levels of meanings: expression meaning, utterance meaning, and communicative meaning. Widespread vagueness in the lexicon should be considered another economic trait of language. Vagueness may occur in combination with polysemy. For example, the meaning variants of *light* are a matter of different underlying scales of weight, difficulty, and so on. Each meaning of scale is vague.

Synonymy

Two lexemes are synonymous if they have the same meaning. Synonymy in the strict sense includes all meaning variants for two polysemous lexemes and it includes all meaning parts; namely, descriptive, social, and expressive meaning.

Meaning and Subjectivity: Expressive Meaning

Anything we say will not only be understood through its denotation or descriptive meaning but also be taken as the expression of a personal emotion, opinion, or attitude. However, a sentence can be spoken in a neutral manner or in a way that exhibits different emotions, for example, desperation or concern but also delight, amusement, or relief. It could be pronounced in a mean or a kind manner, or hastily, or particularly slowly. This general aspect of language use, its expressive function, is not what is meant with the notion of expressive meaning. On a par with descriptive and social meaning, expressive meaning is part of the lexical meaning of certain expressions, a semantic quality of words and phrases independent of the context of utterance and of the way they are being spoken.

The expressions with expressive meanings are called, unsurprisingly, *expressives*. Again, there are two kinds of expressive, those with exclusively expressive meaning and others with both descriptive and expressive meaning. The most typical instances of expressives with exclusively expressive meaning are words and phrases used for directly expressing an emotion, feeling, or sensation, such as *ouch*, *wow*, and *oh*. Such interjections are language-specific. Languages may differ in how many such expressions they have, and an expressive may have different meanings in different languages.

At least some feelings, sensations, attitudes, and evaluations can thus be expressed in two ways: subjectively and directly by means of expressives and objectively by forming sentences with the respective descriptive meaning. For instance, *Ouch!* and *That hurts!* While expressing similar emotions, they are structurally different, the former being the expressive interjection and the latter being an ordinary short exclamation describing the feeling.

The rules governing the use of expressives are simple. Since all expressives serve to express personal feelings, attitudes, or sensations which are perceptible only to the holder, their correct use is just a matter of personal judgment. Interjections and exclamations can be used as complete utterances. Other expressives such as *hopefully*, *(un)fortunately*, or *thank God* can be inserted into a sentence in order to add a personal attitude to the situation expressed.

Meaning and Cognition

During the past three decades, the development of a new branch of science, cognitive psychology, or more generally cognitive science, has given important fresh impetus to linguistics in general and semantics in particular. Cognitive science is concerned with how the human mind works, how it receives information from the environment via the senses and processes this information, recognizing what is perceived, comparing it to former data, classifying it, and storing it in the memory. It tries to account for the complex ways in which the vast amount of information in our minds is structured, and how we can operate with it when we think and reason. Language plays a central role in these theories. On one hand, speech perception and production and the underlying mental structures are major objects of investigation. On the other hand, the way in which we use language to express what we have in mind can tell much about how the human mind is organized.

The importance of cognitive psychology for semantics lies in its emphasis on the exploration of the concepts and categories we use. While semantics in the wider tradition of structuralism aims at a description of meaning relations, the cognitive approach focuses on meanings themselves. It tries to provide positive descriptions of word meanings and thereby to account for why and how words denote what they denote.

The mental act of classifying things and forming categories which underlies cognition in all its aspects is called *categorization*. Traditionally, categorization was held to be a matter of necessary and sufficient conditions (e.g., a bird belongs to the category of penguins if and only if it fulfills the

particular set of conditions that define this category).

This view was challenged by the proponents of so-called *prototype theory*. These cognitivists argued that categories are essentially defined by prototypes—in other words, those examples of a category that come to mind first and represent the most typical cases. Prototype theory led to a radically different view of categorization implying, for example, fuzzy category boundaries and gradual membership. Another significant novelty was the investigation of the hierarchical organization of our category system, with the result of establishing what came to be called the *basic level of categorization*. This is a medium level of generality that is preferred in thinking and communicating. However, many of the central claims of prototype theory, in particular, fuzzy category boundaries and gradual membership, are problematic.

Categorization is only possible if the respective categories are in some way available in the cognitive system; that is, in our mind. In the terminology of cognitive science, categorization requires mental representations of the categories. Categories are represented by concepts for their exemplars. When we encounter an object, our cognitive apparatus will produce a preliminary description of it, which consists of what we perceive of the object: its size, shape, color, smell, and other such qualities. The description will be compared with the concepts we have in memory, and if the description happens to match with the concept, the object will be categorized as such, under the relevant category.

Another important issue is the relationship between meaning and cognition: the distinction between the meaning of a word and the total knowledge we mentally connect to the word. More specifically, this distinction between semantic knowledge and cultural knowledge is important for semantics.

SET THEORY

Set theory is the study of membership in collections of elements or *sets*. Beyond this, set theory can be understood as a symbolic framework with wide applications outside mathematics, yet which

has been applied by mathematicians in two ways: First, set theory can be seen as an approach to advance knowledge of particular mathematical problems, notably as the study of the formal properties of infinity. Second, set theory is seen as a language that allows all of mathematics to be subsumed under one unifying theory.

This entry is divided into three sections. The first explains the core concepts of set theory, including notation and the concept of *cardinality*, or the size of sets. The second section outlines the invention of modern set theory by Georg Cantor (1845–1918) and his counterintuitive discoveries, notably that there are different *sizes* of infinity. The third section describes the efforts by scholars to use set theory as a foundation of mathematics. Finally, the entry summarizes the philosophical division of mathematics raised by set theory: whether mathematics can be understood as the study of something *real* or whether it is a symbol system that is invented or constructed by the human mind.

Despite these debates, and the paradoxes around mathematics, set theory continues to remain as the dominant theory used to unify disparate areas of mathematical inquiry. Moreover, the startling finding by Cantor that infinity consists of different *sizes* is noncontroversial. To begin understanding set theory, it is important to understand some of its basic concepts.

Set Theory as a Formal Language

Set theory is a formal language to define membership relations, as opposed to a natural language.

Formal languages are useful because they specify collections of objects precisely, that is, without ambiguity. Without precise definitions, it is more difficult to communicate abstract relationships and ideas. Applications of set theory are useful for understanding many areas of mathematics and computer science, where precise terms are needed to define objects of inquiry.

As noted in the introduction, a *set* is a collection of distinct *elements*. Elements of a set can be anything, including other sets or nothing at all. Sets with an infinite number of elements are called *infinite sets*, and sets with a finite number of elements are called *finite sets*. Sets are typically represented as capital letters, with a few exceptions. In particular, sets with no elements, or *empty sets*, are denoted by the $\emptyset$ symbol. Other common set theory terms are listed in Table 1.

Elements are listed and separated by commas within curly brackets “{ }” that denote the upper and lower bounds of the set. Ellipses indicate a continuous of a sequence within a set. In addition to listing elements of a set, the *set builder* notation, typically notated using a vertical bar “|” can be used to describe the criterion of a set.

Set theory also uses a stylized form of the Greek *epsilon*, $\in$, to express set membership (*epsilon* is the first letter of the Greek word “is”). Thus, “ $x \in A$ ” means that “ x is an element of A .” If *epsilon* is reversed ($\ni$), then the expression is “ $A \ni x$,” which means that “set A has x as an element.” Conversely, “ $x \notin A$ ” means that “ x is not an element of set A ,” and “ $A \not\ni x$ ” means that “set A does not have x as an element.”

Table 1 Common Set Theory Terms

Symbol	Meaning	Example	Translation
{,...}	set; collection of elements	$A = \{1, 2, 3\}$ $B = \{3, 4, 5\}$	“The set A of elements 1, 2, and 3.” “The set B of elements 3, 4, and 5.”
$\in$	“belongs to”	$1 \in A$	“The element 1 belongs to set A .”
$\notin$	“does not belong to”	$4 \notin A$	“The element 4 does not belong to set A .”
$\ni$	“contains”	$A \ni 1$	“Set A contains element 1.”
$\not\ni$	“does not contain”	$A \not\ni 4$	“Set A does not contain element 4.”
	“such that”	$\{x \mid x > 0\}$	“All x such that x is greater than zero.”

Note: Terms used are to identify membership and their negation. The symbol “|” is also known as *set-builder notation*.

Source: Compiled by Nathan E. Fosse.

Some additional examples of the foregoing nomenclature are shown here. For example, $A = \{1, 2, 3, 4, 5\}$ can be used to mean “the set of the set all integers from one to three.” Sets can have all elements listed or can be described as a criterion for membership. For example, the following set A consists of five elements, wherein $B = \{\text{Liam, Noah, Ethan, Mason, Lucas}\}$. This can also be described as, $B = \{x \mid x \text{ is one of the five most popular boy names in the year 2015}\}$. Alternatively, this set is typically expressed as, “the set B of all x , such that x is one of the five most popular boy names in the year 2015.” As the previous examples show, set theory is a way of defining collections of elements and their relative membership. In this way, sets are useful for clarifying natural language (or everyday language) in more precise terms, that is, by translating natural language into a formal language. Set theory is also a way of linking logical statements and mathematical statements under the same system of language.

A core concept in the study of sets is the determination of their size or the number of elements that sets contain. The absolute number of elements in a set is called its *cardinality*. The relative size of sets is called their *ordinality*. Put differently, the cardinality of a set is the number of elements it contains; in contrast, the ordinality of a set is whether or not it contains more, fewer, or the same number of elements as another set. Thus, two sets are considered the same size or of the same cardinality if they contain the same number of elements. For example, set $A = \text{set } B$ because they exhibit the same size or cardinality; in finite sets, this can be simply a means of counting the number of elements to determine their cardinality. Another way to compare sizes of sets is by their *ordinality*, that is, by whether one is relatively larger than another. Thus, while *cardinality* refers to absolute size of sets, *ordinality* is the *relative* size of sets. The size of sets is the number of elements in them. For finite sets, ordinality is the same as cardinality: That is, the number of elements that are in a set define whether it is larger, smaller, or the same size as another set.

A central insight in set theory is that we can determine whether two sets are of equal size if we can *pair up* each element of one set to another; in set-theoretic terms, two sets are of equal size (the same *cardinality*) if their elements have a

Table 2 One-to-One Correspondence of Two Finite Sets, A and B

A	1	2	3	4	5
	$\updownarrow$	$\updownarrow$	$\updownarrow$	$\updownarrow$	$\updownarrow$
B	Liam	Noah	Ethan	Mason	Lucas

Note: “One-to-one correspondence” means sets compared are the same size (cardinality).

Source: Compiled by Nathan E. Fosse.

one-to-one correspondence. The example is clear with finite sets, although the crucial insight in the study of infinity is that this *matching* technique can be applied to determine the size of infinite sets. The intuition of one-to-one correspondence is clearer when comparing sets A and B as above.

Set membership can be explained in terms of *subsets*. *Subsets* are those sets where every element is in another set. Following this definition, a subset can be equal to a set that contains the same items. Moreover, because every element of an empty set is an element in any set of finite numbers S , every set of finite numbers has as its subset the empty set $\emptyset$.

Two other types of subsets are *proper subsets* and *power subsets*. First, proper subsets are more specific. In set theory, a *proper subset*, for example, is one where K is a subset of A but where the number of elements in K is not equal to A . For example, the set of all Kansans is a proper subset of all Americans. Kansans are a subset of Americans because every person in Kansas is also an American, but the number of Kansans does not equal the number of Americans (in all 50 states). As mentioned previously, elements of sets can be anything, including other sets. Each set not only contains subsets but also a *powerset* that is the set of all subsets in S . Powersets are indicated by the Greek symbol delta (lowercase), δ ; for example, for set S , $\delta(S)$ is the set of all powersets for S . Determining the cardinality of the powerset for any set S with n elements is straightforward: $\delta S = 2^n$. For example, given the example above, set A contains five elements. Accordingly, the powerset of A is 32; that is, there are 32 subsets of set A . Formally, $\delta A = 2^5 = 32$.

Another fundamental set of logical operations between sets concerns their degree of membership

with each other. Three of the most common operations between sets are described below. Below are several of the essential operations in set theory. First, the *union* of sets A and B ($A \cup B$) includes membership to all distinct elements of A and B . Second, the *intersection* of two sets A and B ($A \cap B$) restricts membership to only those elements belonging to A and B jointly, but not to any other elements. Third, the *complement* of set A (also known as the *absolute complement*) refers to anything not belonging to that set A (denoted as A^c). Extensions of the union, complement, and interaction of sets are used to define set membership.

The present treatment is by no means exhaustive; instead, basic concepts were introduced to clarify the language necessary to describe set membership and the relative sizes of sets. A comprehensive source is Paul R. Halmos's 1974 book *Naïve Set Theory*. For a more accessible introduction to set theory and related concepts, see Jan Gullberg's *Mathematics: From the Birth of Numbers* (1997).

The next section describes these applications for infinite sets. In fact, set theory was invented by the German mathematician Georg Cantor for the purpose of studying the relative size of infinity. Before Cantor, there was only a vague concept of infinity but no formal study of its properties. These insights, as will be shown, are counterintuitive and were controversial in their time. However, Cantor's application of set theory was the catalyst for the search for a unifying theory of foundation of mathematics based in set theory.

Set Theory as the Science of Infinity

Set theory is closely linked with the study of the infinite. That is, whereas Cantor believed that set theory is indeed the foundation of mathematics, he invented set theory to develop what he called an "arithmetic of the transfinite numbers" (quoted in Dauben, 1983, p. 112). Accordingly, the beginning of set theory is often marked by the groundbreaking 1874 publication by Cantor, the first published work proving the existence of different *sizes* of infinite number sets.

To understand set theory as the study of infinity, it is important to review different types of number sets and their notation. These types of numbers, their set-theoretic notation, description, and formal definition, are summarized in Table 3.

In particular, the following are typically used to reference number types: N , natural numbers; Z , integers; Q , rational numbers; I , irrational numbers; R , real numbers (notation can also rely on capital letters to describe these number sets: N , Z , Q , I , and R). Other number sets exist (such as complex or imaginary numbers), but these are described and referenced below because they most clearly demonstrate the counterintuitive insights from Cantor's discoveries.

Table 3 summarizes and describes the infinite sets using both natural language and its formal, set-theoretic definition. Note that all of these number sets are *infinite sets*; they continue in a never-ending sequence. Leaving out irrational numbers, let us compare the *ordinality*, or the relative size of these sets, based on the core concepts in the previous section (namely the concept of proper subset and of the union of sets). Taking an intuitive approach to infinite sets, it suggests sets where $N < Z < Q < R$. That is, N is a proper subset of Z , Z is a proper subset of Q , and Q is a proper subset of R . R consists of all possible numbers on the real number line. The informal, verbal description illustrates how these infinite sets intuitively relate to one another: all the following number sets— Z , Q , and R —build successively on the elements of N . To elaborate, Z is the union of natural numbers with positive whole integers and zero. Next, Q is the union of Z (the set of integers) and rational fractions; this is because every integer can be expressed as a fraction: $1/1 = 1$, $2/1 = 2$, $3/1$, and so on. Finally, because the set R is defined as the union of both rational and irrational numbers, it by definition includes Q and its proper subsets.

An intuitive approach to the proper subsets of the infinite set of natural numbers also suggests it contains proper subsets. For example, the number of positive even numbers, $E = \{2, 4, 6, 8, 10 \dots\}$ is, by definition, one half of all positive whole integers. Intuitively, there are fewer even numbers than natural numbers. In addition, one may intuitively conclude that there are fewer odd numbers, squared numbers, and primes; certainly, these are proper subsets if we restrict ourselves a finite set of natural numbers.

Cantor proved, however, that our intuition, based on the study of finite sets, cannot be true. The aforementioned concepts are intuitive when applying to finite sets, but when comparing sizes

Table 3 Common Infinite Number Sets

<i>Notation</i>	<i>Number Set</i>	<i>Informal Description</i>	<i>Formal Definition</i>
N	Natural numbers ¹	Whole positive numbers.	$N = \{1, 2, 3, \dots\}$
Z	Integers	Natural numbers plus their negative counterparts.	$Z = \{\dots -2, -1, 0, 1, 2, \dots\}$
Q	Rational numbers	Integers plus the rational fractions (those that can be expressed as a ratio of two integers).	$Q = \{ p/q : p \text{ and } q \text{ are members of } Z \text{ and } q \text{ is not zero} \}$
I	Irrational numbers	Fractions that <i>cannot</i> be expressed as a ratio of two integers; or, any real number that is not a rational number.	$I = \{ R - Q \}$
R	Real numbers	Rational numbers plus irrational numbers; the continuum all possible numbers on the number line.	$R = \{ I \cup Q \}$

Note: Natural numbers sometimes exclude zero. The essential point is that these numbers are *countable*. Zero is excluded here because of how natural numbers are used in set theory to count the number of elements in a set.

Source: Compiled by Nathan E. Fosse.

of infinite sets we must establish cardinality (absolute size) and ordinality (relative size) by pairing off elements of each set. Recall that two sets are the same size or have the same cardinality if they have a one-to-one correspondence. For infinite sets, we need not pair off *every* element, we only need to show that it is possible to establish a one-to-one correspondence.

By relying on the simple tool of one-to-one correspondences, Cantor proved there are two different levels or sizes of infinity. First, there are *countably infinite sets* that can be paired-off to the set of natural numbers N . These sets are of the same cardinality of N and are described as *countably infinite* because, at least in theory, one is able to count off each element of these infinite sets. The cardinality of these is defined by Cantor as *aleph-null* or $\aleph_0$ (*aleph* being the first letter of the Hebrew alphabet). The *null* subscript is to indicate that these infinite sets are the *smallest* size of infinity.

Second, Cantor found that other infinite sets are *uncountably infinite* because they cannot possibly be paired off with the set of real numbers. Uncountably infinite sets are vastly larger than the cardinality of countably infinite sets, $\aleph_0$. How much larger? Because we cannot establish the cardinality of uncountably infinite sets, we have no way of knowing how much larger, except that we

know that the difference is vast: One should think of countably infinite sets as minuscule compared to uncountably infinite sets. In fact, if we subtract from an uncountably infinite set the cardinality of countably finite sets, $\aleph_0$, *we are still left with an uncountably infinite set*.

Starting with countably infinite sets, the intuition is relatively simple. Beginning with the set of real numbers N , Cantor devised several techniques to *pair off* infinite sets with N . Contrary to intuition, Cantor proved that proper infinite subsets of N , such as the set of even numbers E , odd numbers O , squared numbers S , and prime numbers P , have a one-to-one correspondence with N . In general, there are many other countably infinite proper subsets that are the same size as N ; the point is that, because they have a one-to-one correspondence with N , we can establish that these have the same size or *cardinality*.

Moving beyond proper subsets of N , Cantor developed several ways of establishing a one-to-one correspondence between N and sets that are seemingly larger than N . In particular, by splitting the set of integers Z into odd and even numbers, Cantor showed that every even number and every odd number in Z can be paired with N , despite the fact that N is defined as a proper subset of Z . In the world of infinite sets, N is the same cardinality as Z , as Table 5 demonstrates.

Table 4 One-to-One Correspondences of Natural Numbers N and Proper Subsets

Natural numbers	N	1	2	3	4	...	n	...
Odd naturals	O	1	3	5	9	...	$2n - 1$	...
Even naturals	E	2	4	6	8	...	$2n$	...
Squared naturals	S	1	4	9	8	...	n^2	...
Prime naturals	P	3	5	7	11	...	n th prime	...

What about N and other seemingly larger sets, such as Q , the set of fractions? Here, Cantor again was able to establish a one-to-one correspondence, although this requires more complex diagrams; this is often called the *zigzag proof*. Cantor also showed that the set $N \times N = N$, in a complex diagram called the *zigzag proof*. (Illustrations of these are available in Yanovsky, pp. 74–75.)

In summary, *countably infinite sets* were those discovered by Cantor to have a one-to-one correspondence with the set of natural numbers N . By showing that these sets are of the same size or cardinality, Cantor invented a new language to examine the properties of the infinite.

If Cantor had stopped at the countably infinite sets, he would have found it impossible to prove different sizes of infinity. In fact, Cantor tried but

could not find a one-to-one correspondence between N and the set of all real numbers R (which Cantor also referred to R as the *continuum* or c). Instead of establishing the cardinality of R , Cantor proved that no such possible correspondence can possibly exist between N and R . That is, R is uncountably infinite and N is countably infinite; consequently, R is immensely larger than N . This discovery reveals that, numbers that are rarely identified, notably irrational and so-called *transcendent numbers* (i.e., numbers such as π that are both irrational and nonalgebraic) are far from rare: These numbers occupy most of the real number line.

Cantor proved that the set of real numbers R is uncountably infinite, using the famous *diagonalization proof*. This proof is illustrated in Table 6 and is a famous example of *proof by contradiction* (i.e., starting with a false premise and proving that such a premise cannot be true). The proof proceeds in several steps. First, we define the set of real numbers as the infinite set of real numbers in the interval $(0, 1)$. Each element in the set R , bound by 0 and 1, is itself an infinite sequence of decimals (the position of each decimal is indexed in the columns of Table 6). Second, we assume (incorrectly) that we can pair each element of R we have created with the set of natural numbers N . Thus, each row in Table 6 consists of a possible one-to-one correspondence of a real number and a natural number. Third, we show that, by changing the values of the diagonal numbers by one value (i.e., by changing out .4 to .5, and .9 to 0, and so on) we have now shown that a new number, D , is not in correspondence with the set of natural numbers. In fact, no matter what we do, we can *always* change the values of the diagonals by some increment, proving that the initial premise that $N = R$ is false. Consequently, Cantor's diagonalization proof demonstrates that the set of R is *uncountably infinite*. Whereas the proof illustrates this with the set of real numbers bound by the interval $(0, 1)$, this is true for the full spectrum of real numbers as well.

Besides the set of real numbers R , it can be shown that there exist other uncountably infinite sets. Using the same diagonalization method and proof by contradiction, it can be demonstrated that the assumption that $N = \delta(N)$ leads to a contradiction; more generally, no powerset of set S is the same size as set S . However, because the

Table 6 Diagonalization Proof

		Position (0, 1)					
Natural numbers		1	2	3	4	5	...
	1	.4 .5	5	7	2	8	...
	2	.2	4 5	8	0	0	...
	3	.8	0	9 0	1	7	...
	4	.9	6	0	4 2	5	...
	5	.4	7	4	5	5 6	...
	⋮	⋮	⋮	⋮	⋮	⋮	⋮

Source: Compiled by Nathan E. Fosse.

cardinality of any powerset is 2^n , the powerset of $N = 2^{\aleph_0}$. It can also be shown that $2^{\aleph_0}$ is the same size as R , even though both sets are uncountably infinite. Because Cantor also called the continuous finite set R the *continuum*, he called the powerset of N and the size of R , both with cardinality of $2^{\aleph_0}$, the “cardinality of the continuum.”

However, other powersets are larger than the “cardinality of the continuum.” For example, the powerset of real numbers in $(0, 1)$ will not be in correspondence with $(0, 1)$. Because the number of elements in $(0, 1)$ is $2^{\aleph_0}$, the powerset of $(0, 1)$ is $2^{2^{\aleph_0}}$. This, by definition, is larger. Even higher powersets are possible, and none can be put into a one-to-one correspondence with each other.

In summary, this section has shown that Cantor’s discoveries of set theory in the late 19th century developed a new, formal method for studying the properties of infinity. Cantor proved the existence of two types of infinity: (1) countably infinite sets of cardinality $\aleph_0$, equal to the set of natural numbers N ; (2) uncountably infinite sets of cardinalities, which are equal in size to the set of real numbers R , or greater, ad infinitum. One important question is whether there exist any infinite sets of intermediate size, greater than the cardinality of N and less than the cardinality of R (the cardinality of the continuum). Cantor’s famous *continuum hypothesis* is that there is no infinite set between the cardinality $\aleph_0$ and the cardinality of the continuum (which, if true, would mean that the continuum could be expressed as $\aleph_1$). However, later mathematicians, notably Kurt Gödel and Paul

Cohen, established that the continuum hypothesis could not be proven or disproven given existing axioms; mathematically, it is *undecidable*.

Set Theory as a Foundation of Mathematics

Following Cantor, the development of set theory was largely informal, without a system of axioms to clarify assumptions are adopted when applying set theory. The major flaw with Cantor’s informal or *naïve* set theory is that it is *inconsistent*; that is, it contains paradoxes. Thus, by the early 20th century, it was clear that set theory required a system of axioms to precisely state the basic assumptions required. The most obvious reason for developing axiomatic set theory was to avoid paradoxes identified paradoxes when informal set theory is self-referential. The most famous is *Bertrand Russell’s paradox*, dealing with *universal sets* (or the “sets of all sets”). Because universal sets by definition include everything, including themselves, a universal set that excludes itself is a member of itself if and only if it is not a member of itself. In formal terms: $U = \{x \mid x \notin x\}$. The question then is: Does U contain itself?

To avoid this paradox, as well as to clarify other features of set theory, Ernst Zermelo and Abraham Fraenkel developed an axiomatic system of set theory that is widely referred to as *Zermelo–Fraenkel theory* or *ZF theory*. A more controversial variant of this axiomatic theory incorporates the Axiom of Choice, which, for subtle reasons, is included to address concerns regarding properties of infinite sets. ZFC, accordingly, refers to ZF theory with the Axiom of Choice. Despite controversy regarding ZFC, ZF theory is the most widely accepted axiomatic set theory. Based on eight axioms, ZF set theory can show that the majority of modern mathematics can be expressed as sets.

Set theory is still largely considered to be the foundation of modern mathematics. However, as Gödel proved with his famous *incompleteness theorem* in 1931, any logical/mathematical system that relies on axioms cannot be both consistent and complete. Moreover, in practice, as noted by Stephen Pollard, set theory has been only a patchwork theory, falling short of its goal as a grand, unifying theory of the mathematical universe. Despite its limited success as a metamathematical theory, why has axiomatic set theory remained as

the most widely accepted means of integrating mathematics?

There are four reasons for the widespread, continued adoption of set theory as a viable theoretical foundation. First, set theory remains useful for integrating and unifying disparate subfields of mathematics. Since the late 19th century, mathematics has specialized tremendously, from about 40 areas of specialty to at least 3,000 or more areas of specialty in the third decade of the 21st century. Consequently, set theory is useful for communicating and unifying research as the field of mathematics becomes increasingly specialized.

Second, set theory is widely entrenched in mathematics because of path dependency: Put simply, generations of professional mathematicians have been educated in set theory and socialized into adopting its theoretical paradigm. Despite Cantor's controversial findings, modern set theory is relatively uncontroversial. Third, although not complete, set theory is still relatively comprehensive and useful enough to integrate and define basic concepts. Fourth, as of the time of writing, axiomatic set theory has not resulted in any identifiable paradoxes. Finally, notwithstanding many gaps in set theory, no other competing theory has been widely accepted enough to be sufficient to address present knowledge gaps any better than set theory.

It remains to be seen whether set theory will ever be the unifying foundation for all of mathematics. There are undoubtedly supporters of axiomatic set theory. Despite the utility of axiomatic set theory, it has yet to be determined whether ZF set theory is consistent. So far, ZF set theory has not resulted in any inconsistencies despite its development in the early 20th century. On the other hand, as Gödel's incompleteness theorem states, the consistency of ZF theory will never be provable using standard mathematics. In short, there may never be any way to determine whether ZF set theory is consistent.

Conclusion

Set theory has shown great promise for integrating many aspects of mathematics and for developing a formal language that incorporates logic and mathematics. However, set theory raises important questions regarding the nature of knowledge: Are there really such entities as infinite sets despite

the fact that they do not exist in our observable reality? In short, are we discovering anything real with set theory, or are we *inventing* concepts and their relations in an elaborate formal language? Moreover, debate continues regarding the application of axiomatic set theory. Specifically, why should we accept some axioms as self-evident while rejecting others? As Noson Yanofsky points out, there are no simple answers to these questions; more work remains to be done.

SOCIAL CONSTRUCTION OF SCIENTIFIC KNOWLEDGE

There is no one single approach to the study of the social construction of scientific knowledge. The more conservative orientations analyze the institutional, professional, and normative aspects of science while still implicitly maintaining the realist assumptions of the disciplines they investigate. More radical forms view objective facts as constructed and hence contingent on a number of social factors, that if prearranged differently, may result in alternative scientific outcomes and knowledge. Despite this diversity, the organization, professionalization, and overall practice of science, like all human endeavors, are inevitably social. The work of scientists and the subsequent knowledge

their activities produce contain a combination of interpretive processes similar to the mundane social practices of everyday life. But because science is equated with reason, progress, and truth, and, relative to other institutions, enjoys unrivaled authority, many tend to overlook its social context. It was not until the mid-20th century that science became an object of sociological study.

Acknowledging that scientific knowledge is socially constructed does not necessarily imply that it is not a reflection of reality. What it does suggest is that people have to come together to interpret, negotiate, and communicate with one another to make the findings of science possible, meaningful, and legitimate. Moreover, the naïve and taken-for-granted realism and reification embedded within science motivated many sociologists, philosophers, and historians to problematize its reputation as constituting pure fact, objectivity, and universality. This mandate is not without controversy, as it has been perceived as attacking the work of science and undermining the very foundations from which its knowledge is established and made credible.

Robert Merton and Institutional Imperatives

The institutional approach to the study of scientific knowledge dates back to the 1940s with the pioneering work of Robert Merton. Rather than problematizing the objectivity and unity of science, he was more interested in understanding the social forces and institutional factors that shape an ideal form of science. Merton described the universal norms and values that allow for science to function properly. He listed four major institutional imperatives: *universalism*, *communism*, *disinterestedness*, and *organized skepticism*. Merton described universalism as the institution's capacity to evaluate scientific output independent of the individual characteristics of those who contribute findings. Gender, race, and religion do not play any role in the system's ability to reward scientific achievement. Communism represents the accumulation of scientific knowledge as a collective achievement that is to be shared freely, and not hoarded or protected as individual property. Disinterestedness reflects each scientist's concern for overall knowledge at the expense of their own self-interest and personal promotion; truth is prized over all other motivations. Finally, organized

skepticism suggests that scientists scrutinize their own and their colleagues' results until consensus in the community is achieved. When researchers deviate from these imperatives, Merton believed that the system would correct itself through sanctions. This institutional approach explores the professional and normative aspects of science while still implicitly maintaining realist assumptions. Although science as an institutional organization is investigated, its truth claims are taken for granted. If anything, the normative structure of science accounts for how and why this institution is excellent at providing truth and eliminating the potential for personal, social, and political biases.

The Ambivalence of Science

In 1974, Ian Mitroff critiqued and expanded upon Merton's idealized vision of science with his own *counter-norms* of particularism, individualism, interestedness, and organized dogmatism. Mitroff found these norms by talking with a number of moon scientists who were debating the advent of new data, which might support or hinder their own and their rivals' hypotheses. The scientists in Mitroff's sample were not always judged by their peers independently of their social attributes, since the professional reputations of scientists would go a long way in how people would value their contributions and trust their findings. He also showed that researchers are not a unified collective with their results belonging to the community as a whole, committed to a primary goal dedicated to scientific knowledge and progress. Rather, scientists can be quite protective of their own discoveries and often seek their own self-interest, motivated by personal success and recognition. Finally, Mitroff found that scientists are not solely committed to a balanced approach of critically evaluating their own work and that of their peers, but instead tend to view their own discoveries as more objective and valuable than others. Indeed, scientists had a great stake in proving their own theories as superior to others, and many passionately fought to realize their version of the truth over their rivals. In this way, the scientists' pet scientific theories would very much structure their approach to interpreting the data at hand. Mitroff's case study uncovered the ambivalence inherent in scientific research, as it would often oscillate between norms and counter-norms.

Both Merton and Mitroff studied the social organization of science and the attitudes and expectations researchers have of themselves and each other. They both provided normative explanations of how science manages to function. The difference in their work appears to be how science organizes itself. Is it a collective venture with norms providing the necessary conformity and discipline for trusted knowledge to emerge, or are their *counter-norms* acting as well, that are individually negotiated through the fact that scientists cannot help but be human, passionate about ideas, and self-interested? These contrasting motives represent a continuum of expression. Scientific social worlds, like any other institution, operate according to both collectivist and individualist logics. Although their analysis was sociological, Merton and Mitroff did not directly address the social construction of scientific knowledge. This neglect resulted in a series of critiques, with many accusing them of functional explanations, conflating traditional scientific ideology with actual research practice. Scholars would turn away from these schools of thought and find inspiration in the work of Thomas S. Kuhn, who considered how scientific knowledge actually accumulates and radically changes through history, rather than how it ought to work in ideal normative conditions.

Thought Collectives and Paradigms in the Construction of Scientific Knowledge: Fleck and Kuhn

The premise that scientific knowledge is socially constructed took shape during the mid-1930s with the Polish biologist and physician Ludwik Fleck's (1896–1961) research into the subjective nature of scientific facts. His findings led him to suggest that scientific *truth* claims are problematic because they are not passively discovered but rather generated by subtle moral and social processes. He argued that established scientific knowledge is interpreted and organized around *thought collectives* that change over time. These socialized ways of observing and interpreting data are discriminate. Facts are not solely true or false based on their more or less accurate representation of reality but are rather much more ambiguous in that their acceptance must align with the interests and goals of a community of experts. The training

of scientists tends to generate reified *thought styles* that influence and constrain the way data are interpreted and organized. Social, political, and historical contexts play a role in how specific scientific concepts win out over others. Alternative interpretations of evidence are excluded or ignored not because they are less valid but because they lack the backing of a strong *thought collective* and threaten the favored concepts these communities employ. Fleck was one of the first researchers to demonstrate that scientific knowledge is not a direct reflection of empirical evidence but that evidence is often interpreted in ways to fit prior theoretical conceptions and assumptions.

Despite Fleck's keen analysis, his insights remained ignored for decades. It was not until the 1960s and 1970s that Fleck's work began to be taken more seriously. Thomas Kuhn (1922–1996), a physicist and historian of science, credited the work of Fleck and expanded on a number of his themes in crafting his own massively influential thesis on the social nature of scientific change. In his book, *The Structure of Scientific Revolutions*, Kuhn describes the advancement of scientific knowledge not as purely cumulative and rational but as a result of sudden and disruptive changes in belief or *revolutions*. Standardized questions, theories, methods, and standards of evidence, known as *paradigms*, are modeled after the work of exemplary scientists and then entrenched in the professional education and socialization of scientists and the implementation of scientific practices to follow. These convergent ways of knowing and doing achieve prolonged states of *normal science*, whereby scientists spend most of their time in puzzle-solving. This means that rather than seeking out new radical ideas, scientists take on faith the core theories of the paradigm and merely try to figure out how to fit the empirical world into the conceptual boxes that flow logically from the theory at hand. According to Kuhn, this practice of normal science is the conventional everyday practice of science. Similar to Fleck's thought collectives, normal science demands conformity from scientists in that their interpretation of experimental results corresponds to the preestablished general consensus provided by the ruling paradigm. Scientific research that is not supported by conventional models and deviates from the dominant paradigm is rarely successful. For Kuhn, science

lacks authentic critical self-reflection and, ironically, innovates best when scientists conform rigidly to, and doggedly adhere to, previously held paradigms of thought. Rather than allow researchers the freedom to question the implicit assumptions and biases underlying normal science, the dominant paradigm forces practitioners to conform to conventional standards. Counterevidence and anomalies threaten a paradigm and are thus heavily sanctioned or ignored by the majority of supporters of normal science who have built their careers and reputations around its basic tenets.

Paradigms as Interpretive Constraints

Both Fleck and Kuhn claim that scientists' collection of data and evaluation of evidence tend to be tightly bound to their paradigm's underlying theoretical assumptions and predetermined rules of interpretation. David Rosenhan provides a salient example of a medical paradigm's power to force conformity. His experiment questioned the taken-for-granted assumption that expert systems of medical knowledge are purely objective and demonstrated the routinization, social construction, and overall constraining force of paradigmatic inertia. Specifically, Rosenhan offered a critique of the subjective nature of psychiatric diagnoses in the modern era. He asked, "If sanity and insanity exist, how shall we know them?" His answer had a profound impact on the mental health community. The Rosenhan experiment consisted of eight research associates who, on the basis of their false claims of hearing voices they defined as *hallow* and *empty*, admitted themselves to psychiatric hospitals for the sole purpose of seeing whether medical experts could identify them as sane. On this basis alone, Rosenhan's *pseudo-patients* were misdiagnosed with schizophrenia. After they were admitted, they acted normal, were honest about their life histories with hospital staff, and informed them that the voices had ceased. Despite their sane behavior while institutionalized, nurses and psychiatrists did not view pseudo-patients as *normal*. Much like the reification tendencies inherent in Kuhn's paradigms and Fleck's thought collectives, Rosenhan found that labels associated with mental illness act as conceptual frameworks in which hospital staff interpreted patient interactions. Rosenhan's conclusion is that experts interpret

and process all patient behavior solely as indicative of a presupposed underlying pathology. The irony here is that although psychiatrists could not detect the sanity of Rosenhan's research associates, labeling them as *schizophrenia in remission* upon their discharge, actual hospitalized patients did in fact see through the ruse. Rosenhan suggested that if psychiatrists could not detect the sanity of their pseudo-patients, then the true validity of the diagnoses resided not in an individual's inherent nature but in the framework of expectations provided by the environment and organization itself. That is, the suffering of mental illness is real, but the diagnostic process is paradigm dependent and socially shaped by theoretical expectations.

Gestalt Shifts and Incommensurability

In spite of paradigmatic communities' reluctance to change, revolution is unavoidable. Scientists eventually become unsatisfied with conventional treatment of anomalous data, and as this evidence grows, the validity of their theoretical models becomes impossible to sustain. This inadequacy results in the paradigm's falling into crisis, initiating a competition among new, often incompatible paradigms as to which will move in to take the place of the prior paradigm. There is an intense antagonism between the normal science of the old paradigm, which dismisses an anomaly and defends its ground, and new paradigms that embrace the anomaly as vital to their theoretical validity. Scientists choose one of these competing paradigms, with the old guard of normal science eventually being replaced by younger revolutionary converts. Kuhn argues that theory choice is not solely based on logic, since none of the new paradigms have yet had a chance to prove their worth. Instead then, persuasion, rhetoric, and social-psychological factors play a major role in influencing what emerging paradigm wins out. Once this new paradigm is established and is seen as superior to that which came before, Kuhn describes a *paradigm shift*, which represents a gestalt shift in the scientific community. A new paradigm allows scientists to view evidence differently and make sense of anomalies within a new epistemological context. This is the revolutionary nature of scientific change. These rare gestalt shifts have scientists reconfiguring the way

evidence is interpreted, which are counter to the explanations provided by previous paradigms. Kuhn believed that new paradigms are always incommensurable with those that came before. After a scientific revolution, Kuhn suggests that scientists are no longer able to explain current findings under the old paradigm. Evidence is seen in a completely new way. The nature of scientific problems and their solutions are redefined. He provides the displacement of Aristotelian science by Galileo's physics as an example of a paradigm shift and leading to incommensurable ways of seeing the world. Given the motion of a swinging stone on a string, each observer would view its motion differently. Aristotelians would view a swinging stone as a falling body whose nature and *desire* is to rest at the center of the earth, but due to the string, it can only fall with difficulty. Galileo would interpret the same swinging body as a pendulum, which almost achieves an infinite periodic cycle. This is an excellent example of the gestalt shift that accompanies paradigm change; the same physical phenomenon is seen according to an entirely different system of logic and interpretation. It was not a matter of the new paradigm being a better reflection of reality, but rather it constituted a whole new way of viewing reality that was inconceivable prior to Galileo.

Revolutionary paradigms eventually settle and become established, thus transforming into normal science. This period has its own new generation of researchers who conform to the convergent set of expectations of what makes for good science and true theories. The previous crisis and subsequent revolution are made invisible in scientific textbooks, while it is made to look as though the new paradigm were an inevitable and conservative progression from the old rather than a radical and discontinuous shift, as the new paradigm settles into business as usual. Yet Kuhn's incommensurability thesis problematized the popular view of science as a cumulative and always progressive march toward a greater stock of objective truth about the world. Accentuating the subjective, cyclical, and collective nature of scientific change, the notion of scientific revolutions, and the incommensurability between paradigms that would result became the most contested and influential aspect of Kuhn's work.

Seven years after the original publication of *Structure*, Kuhn answered his critics and clarified

his incommensurability thesis. Specifically addressing the translation problems thought to exist between paradigms, Kuhn acknowledged that scientists have the potential to see different viewpoints without experiencing the gestalt shift that he once described as tantamount to conversion. This process is possible as long as each discipline refrains from the dogmatic bias that tends to contextualize the other's foundational axioms as trivial anomalies relative to their own favored paradigm. Striving toward cooperation and not necessarily consensus, they can each come to understand contrasting theories in their own terms while being sensitive to alternative interpretations. Kuhn admits that this hermeneutic exercise is essentially how historians of science conduct their own research.

Trading Zones and Boundary Objects

Peter Galison's *trading zone* metaphor extends Kuhn's insights regarding the role knowledge translation plays in transcending paradigmatic barriers. These zones are characterized by what Galison calls interlanguages and boundary objects. The construction of a localized pidgin or creole along with the identification and maintenance of shared technical-social objects, which despite having different meanings accorded to each group, act as a symbolic bridge that links the parties together for a limited time so that ideas and resources can be traded without compromising the integrity of their prescribed paradigms. Many multidisciplinary case studies have since demonstrated how two or more different scientific subcultures with competing interests can exchange information and translate their perspectives across disciplinary boundaries without experiencing a gestalt shift or the threat of conversion. For Adele Clarke and Joan Fujimura, communities of science that may be divided by different paradigmatic logics of theory and practice can cooperate by the use of common and relevant boundary objects that help to unite otherwise divided professional and scientific social worlds. Furthermore, Susan Leigh Star and James Griesemer argue that boundary objects not only build common ground across scientific subcultures but can also facilitate knowledge translation between scientific experts and intersecting nonscientific social worlds. Benjamin Kelly importantly points out that such boundary

agreements are not always entirely fair and often become structured depending on power imbalances and inequalities between the participants.

Although Kuhn's account of science is more descriptive and relativist than Merton's prescriptive treatment, many have accused Kuhn of being too conservative in his understanding of scientific legitimacy and change. Pierre Bourdieu (1930–2002), for example, would emphasize the importance of unequal scientific capital in determining scientific change and the restructuring of academic fields. Kuhn's work nevertheless provided the foundation for what is known today as *Science and Technology Studies*. Kuhn inspired a whole generation of social constructionists who set out to problematize objective truth claims and begin to analyze the human side of how scientific knowledge is produced.

The Strong Programme and Laboratory Ethnographies

The social philosophy of science laid down by Kuhn opened the way for historians, sociologists, and anthropologists to begin to conceive of science as a rich new area to study the sociology of knowledge. Up until that time, following the work of Karl Mannheim (1893–1947), sociologists tended to treat scientific knowledge as an exception to other modes of knowledge, such as religion and politics, as a potential subject for ideological deconstruction. Mannheim followed Karl Marx in critiquing the content of knowledge in societies as ideological and distorted but always assumed that scientific knowledge was immune from these influences. This exceptional character of scientific knowledge was based on the notion that science rested on rigorous methods, such that it was beyond the level of simple claims from authority. In science, all claims had to be subjected to the careful scrutiny of systematic empirical tests. This is what Popper might call the role of *crucial experiments*, used to test whether or not given claims ought to be believed, by continued attempts at falsification through intersubjectively shared empirical experiments. But if Fleck and Kuhn were correct, that observation and experiment are themselves shaped by prior theoretical beliefs, which in turn are based on paradigms of theoretical and methodological convergence around long-held scientific cultural histories, perhaps the knowledge scientists develop in the laboratory is also open to sociological analysis. That is, like all

forms of cultural knowledge, scientific knowledge too might be socially constructed.

Edinburgh's Strong Programme

In the 1970s, several sociologists inspired by Kuhn's work launched a new campaign to try and study the socially constructed nature of scientific knowledge. David Bloor's *strong programme*, originating from the Edinburgh school in Scotland, was most famous for developing a kind of manifesto for studying the socially constructed aspects of science. The strong programme adhered to four central tenets: (1) It would be causal in that it would focus on how social conditions and processes led to the development of scientific knowledge; (2) it would be impartial with respect to truth and falsity, as both true and false beliefs equally require sociological explanation; (3) it would be symmetrical in its style of explanation. In other words, there would not be a unique method to investigate beliefs deemed to be true versus those deemed to be false; and (4) it would be reflexive, such that in principle its patterns of explanation about scientific knowledge could also be turned around and applied to social-scientific knowledge as well. This school of thought became quite controversial in that scientific knowledge was posited to be relative to social interests, structures, and processes; indeed, its final thesis of reflexivity meant that even sociological knowledge was now seen to be on shaky ground since it also had to be seen as a cultural construct over and above a direct correspondence with reality. A related school of thought to the strong programme was that of *interests theory*, put forth by Barry Barnes. This was an attempt to explain the content of scientific knowledge that was generated by certain groups based on macro-sociological variables such as social class, gender, and political affiliation. These variables were applied by Barnes to consider why, for example, certain theories of evolution, brain chemistry, or Mendelian genetics might have been shaped by the ideological interests of the scientists at work in these times.

Ethnographic Laboratory Studies and the Experimenter's Regress

As the strong programme was starting to make waves, the sociologist Harry Collins pioneered the tradition of ethnographic laboratory studies. He

began to visit scientific laboratories across England with the hope of investigating firsthand how scientific knowledge might be socially shaped. Studying the replication of lasers, Collins showed that laboratory technologies such as the lasers were not easily built. In fact, it took months and even years for some scientific groups he studied to correctly assemble and finally fire the laser. This is because constructing lasers took on a craftlike character and required a good amount of tacit knowledge over and above purely codified forms of knowledge. This finding was a direct challenge to Popper's assumption that experiments can easily be replicated in order to try and falsify tentatively held conjectures, since replication itself was not always easy or even possible. This point became even more evident as he began to study the scientific controversy surrounding the existence of gravity waves. Although everyone can agree when a laser has fired correctly, it is more controversial to know whether or not a gravity wave detector is functioning correctly. This is because the scientific community was split as to whether these theoretically exist and can in principle be detected from Earth. Does a true gravity wave detector show signs of the phenomena of interest, or should it, if correctly built, show nothing? Collins found that judgments of whether experiments were run properly depended largely on the previous beliefs scientists carried about the theoretical existence of gravity waves in the first place. This is what Collins refers to as the *experimenter's regress*, the idea that there is no neutral place for observation to settle scientific controversies, since interpretations of what should be observed and what the results mean are always linked to prior theoretical assumptions. Instead of one important *crucial experiment* to settle the controversy of gravity waves once and for all, Collins showed how social influences such as the idiosyncratic perceptions of scientists' professional credibility are more important in bringing about closure. His belief in the importance of social and micro-political processes in the shaping of scientific opinion led to his research program of *empirical relativism*. Here, he would actively seek out open scientific controversies, since what was actually true and false were still in process and up for debate between rival scientific groups. His work with Trevor Pinch to analyze scientific controversies as a way into viewing the *interpretative*

flexibility of scientific findings while observing social and political pressures impacting this became extremely influential.

Anthropological and Ethnomethodological Investigations

Bruno Latour and Steve Woolgar produced their own anthropological investigation of a science laboratory in the 1970s, taking issue with the idea that scientific facts were *discovered*, and arguing instead that they are more accurately understood as socially constructed artifacts. Analyzing the case of scientists working on the discovery of thyrotropin-releasing factor (TRF), they argued that what began as tentative claims about the potential existence of TRF became more and more *fact-like* and objective as it became applied and circulated through the spread of scientific publications. Thus, it was not further experiment that led to more certain claims about the existence of TRF but rather the social process of *black-boxing*, the once tentative conjecture into a stabilized fact. What started as a local uncertainty was transformed into a global certainty through the process of scientific communication, serving to reify the belief.

Karin Knorr-Cetina also entered into laboratory sites using an ethnographic approach in the early 1980s, arguing for the artificiality and decision-impregnated aspects of scientific experiments, and calling into question any notion of true neutral observation unshaped by previous theoretical beliefs. Theoretical beliefs could be seen as bound up in the technologies of the laboratory. Latour and Woolgar referred to these technologies as *inscription devices*, since algorithms were used to generate numeric print-outs instead of enabling direct observations of sensory phenomena. Knorr-Cetina would show the *indexicality* of laboratory processes, in that research decisions are not made entirely on rational grounds but also are subject to the availability of equipment and the methodological and practical norms at play in the local environment. Later, she would study how different laboratories and sciences operated according to different standards of practice, or what she called different *epistemic cultures*. Sharon Traweek would likewise study the cultural differences between how scientific evidence in high-energy physics was dealt with in Japan versus the United States. Michael Lynch would utilize an ethnomethodological approach to

consider how local contingencies shape scientific practices, how the verbal nuances of shop-talk reveal processes of uncertainty, and how observation and experiments are often manipulated and controlled in ways to present certain versions of reality over others. Many other studies of laboratories followed, all trying to argue for the sway of paradigmatic beliefs, theoretical motivations, social and political contingencies, and institutional cultures that led to the social construction of scientific knowledge in varying ways.

Incorporating Nonhuman Actants in the Social Construction of Scientific Knowledge

Latour eventually came to a different conception of the relevance of laboratory studies by the early 1990s. He argued that while the goals of these studies were to show how scientific knowledge is socially constructed, they actually showed there was much more happening “on the bench” than the mere realization of previously held social and theoretical interests. Latour argued that not only do scientists have agency in shaping the construction of scientific knowledge but so also do a range of nonhuman actors in the laboratory, which often act against the interests of the scientists involved. Thus, in Steven Shapin and Simon Shaffer’s study of the debate between Thomas Hobbes and Robert Boyle in the 1660s about the existence of a vacuum, public experiments would be run with an air pump, and the settlement of these scientific controversies would often rest in the hands of what Latour called *nonhuman actants* (in this case mice suffocating, or candles going out), that were enrolled in the experimental setting to convince the public of one side of the debate. Andrew Pickering would similarly argue that a close ethnographic examination of experiments reveals what he calls the “dance of agency” between human and nonhuman actors as they exchange active and passive roles through the process of observational work through time. Latour would take this as a launching pad to critique social constructivists, whom he accused of the modernist error of trying to purify the world of human ideas from the world of nature, and privileging the former in explanation of the latter. If we could only retie the production of knowledge to what he refers to as the *middle-kingdom*, the place where the complex processes of mediation between

human and nonhuman actors happen in a common world, we would have a much better understanding of how knowledge gets made in the messy, practical contexts of “science in action.”

Criticisms of Social Constructionist Perspectives

The constructivist sociology of science has been criticized for being gender blind. Sandra Harding critiques mainstream science (and the sociology of science) as masculinist and Eurocentric and proposes instead a new successor science based on her belief in standpoint theory. She argues that groups who are marginalized in society have a better grounding for, and interest in, generating truth claims that are undistorted by the biases of the dominant and often patriarchal status quo. Her work has inspired many, such as Emily Martin’s study of the problematic masculine assumptions that lie behind the science of human reproduction, and Donna Haraway’s analysis of how constructions of primate society reflect certain patriarchal definitions of the family. Donna Haraway would depart from Harding’s strong version of standpoint theory, however, and argue that all positions, whether marginal or not, are limited by their location that permits only a partial perspective on reality. Pierre Bourdieu was also critical of traditional constructionist accounts in that they would miss the fact that the laboratory sites studied were embedded in wider institutional power struggles between competing actors in the structured hierarchy of science. Stephan Fuchs provides a similar argument that scientists’ location on the institutional fringe, frontier, or center of scientific networks will largely determine the type of research questions (e.g., in Kuhn’s language, either normal or revolutionary) are pursued. Thus, a better institutional, contextual, and macro-sociological approach to the sociology of scientific knowledge would help to rebalance the field by providing a better understanding of the myriad forces that affect scientific knowledge production across the range of settings in which it is realized.

Controversy and Future Directions

In 1996, Alan Sokal, a professor of physics at New York University, published an article entitled “Transgressing the Boundaries: Toward a

Transgressive Hermeneutics of Quantum Gravity” in the postmodern journal *Social Text*. Sokal combined a number of ideas from quantum physics with a variety of postmodern concepts to demonstrate the relativist and subjective nature of reality. After its publication, Sokal confessed that his writing was not an authentic contribution to a postmodern view of reality but a nonsensical mishmash of sophisticated terms woven together illogically. In other words, it was announced as a hoax. His practical joke, which became known as the *Sokal Hoax*, was designed to demonstrate the absurdity of postmodern theory, and further, of the social constructionist perspective on science. His goal was not only to reassert the validity of realism and the scientific method in the hopes of revealing the anti-scientific agenda of social constructionists but also to awaken the Left from its nonsensical postmodern vision of progress. This was a direction, Sokal believed, that was undermining democracy and positive political change. Many STS scholars took offense and attempted to correct what they believed was Sokal’s misguided assessment of their work. The heated debates that followed were known as the climax of the science wars, which had been brewing for years between traditional realist philosophers, natural scientists, and this new emerging relativist school of social constructionism from the 1970s. With no clear winners, one unintended consequence of the science wars was the political Right’s ability to promote anti-intellectualism. Philosopher James Robert Brown argues that the Sokal Hoax uncovered something more important than the legitimacy of the social construction of science. He suggests that it exposed the political undercurrents behind attitudes toward science and argues that the science wars and Sokal’s hoax informed the public that the antagonistic or favorable views toward orthodox science are much more complicated than the common but false “anti-science Left versus pro-science Right” dichotomy.

Since these debates, the sociology of scientific knowledge has begun to expand its range and scope. Following Latour’s earlier advice to “follow scientists around society,” recent scholars have examined how science and experimental work play out and have relevance for an array of topics as wide as the social and cognitive sciences, education, medicine, genetics, politics, forensics and crime, scientific governance, the environment, economics,

law, the public participation of science, as well as multicultural and global issues of knowledge production. What has remained is a dedication to detailed historical and ethnographic case studies to uncover the micro-sociological practices that show how local contingencies, politics, and negotiations are crucial to understand how knowledge is sedimented, universalized, and spread. This approach of local, fine-grained ethnographic analysis has also extended outward into questions concerning technology, its relation to science, and its incorporation and reshaping in relation to everyday users across a range of social contexts. What began as a trail-blazing exercise in trying to push for radical and relativistic epistemologies of science from the 1970s has morphed into a well-institutionalized and respected approach to the study of knowledge production, with a range of interdisciplinary applications. The sociology of science remains a field ripe for investigating the structuring role of theory in knowledge production and how such theories are always richly embedded in culture.

SOFTWARE ENGINEERING

Since the terms *software* and *software engineering* (SE) began to be used, they have undergone significant changes. While the meaning of the former has evolved from a specific program to a complex product, the latter has become a professional discipline affecting almost every industry. Spectacular improvements in hardware, memory, and storage capacity, along with the new computing architectures, have paved the way for sophisticated computing systems over the past five decades. Today's world cannot be run without software, and our global society could not function without professional software systems. Software is embedded inside everything from simple consumer electronics to medical systems to command and control systems. Therefore, it provides a gateway to worldwide information networks; infrastructures, transportation, industry, and financial systems are all controlled by computer-based systems. SE has become critically important, and therefore, software engineers have responsibilities both to the engineering profession and society.

SE is an applied discipline encompassing processes, methods, tools, and principles in order to build reliable, maintainable, and large-scale software systems with high productivity and quality. The inherent constraints in SE stem from its intangibility, complexity, and human dependency, and thus, the main problem in SE is generally viewed as that of making the connection between the abstract world and the physical world. To that aim, software engineers are concerned not only with technical issues but also the conceptual and theoretical background of SE as a discipline. Theory provides a conceptual framework for organizing facts and knowledge, it helps understanding the underlying mechanisms of software systems, and finally, it facilitates communication of ideas in

SE community as well as in SE research area. From an evolutionary point of view, SE can be regarded as a young discipline; however, it has transdisciplinary and theoretical foundations that incorporate multifaceted principles in other disciplines while allowing the development and use of SE-specific theories. After defining SE and noting its key concepts of SE, the entry goes on to describe the nature of software, SE as a discipline, its theoretical and transdisciplinary foundations, and the development and use of theory in the research and the software industry.

Engineering as Concept and Profession

Engineering is an applied discipline as well as a technological and problem-solving approach in which complicated artifacts are systematically planned, designed, developed, and maintained on the basis of scientific theories and principles. As a profession, it is defined by the Accreditation Board for Engineering and Technology (ABET) as “the profession in which knowledge of the mathematical and natural sciences gained by study, experience, and practice is applied with judgment to develop ways to economically utilize the materials and forces of nature for the benefit of mankind” (ABET, 1986, n.p.). Therefore, the use and choice of appropriate tools and methods is the key to engineering when playing the roles such as research, design, development, production, testing, and maintenance during engineering processes.

The concept of engineering, which emerged from the times of manufacture-based and mass-production-oriented industrial revolution, is a methodology for achieving a common goal with a group of people working together, which could not be done by individuals technically, physically, or economically. Science accumulates and organizes the theoretical and empirical knowledge for solving technological and engineering problems. While scientists perform research to create new theoretical knowledge, engineers convert this knowledge into practices, applications, devices, and processes for the design and development of products. In other words, scientists seek to know and explore what is, and engineers find out how to do. As a result, engineers perform, calibrate, and validate measurements; make approximations based on experience and empirical data; and work quantitatively whenever possible.

Software: Definition and Function

The term *software* is credited to John W. Tukey, a statistician and chemist, who first used it in print in 1958. SE, as a concept, was initially used in a North Atlantic Treaty Organization conference in 1968. Software can be defined as the computer programs that are made up of instructions running on different types of computer systems and devices, providing users with desired functions and performances and enabling users to process and manipulate data. Software is logical rather than physical, and therefore, it has substantially different characteristics than those of hardware. It is not only another word for computer programs, it also includes associated documentation and configurations required to make a program work properly. A *computer program* is the code created by a programming language or the algorithm plus data; *software*, however, is an integration of the program code with design and supporting documentations, intermediate work products including system specification and design, decisions, code configuration, test cases, maintenance, and user manuals.

By playing a dual role, software can be a product or it can be a means to deliver a product acting as the basis for the control and creation of tools and environments. Software can be generic or customized. The former is the stand-alone system developed by an organization and sold on the open market, while the latter is delegated by a particular customer to a software contractor and then developed specifically for that customer. It is also possible to categorize software into the groups such as system software, application software, product line software, scientific software, embedded software, web application, and so on, each in turn having a unique context. From the viewpoint of a software engineer, a software product is the combination of programs, data, and other computer software. In addition, this product can be viewed by a software user as a means to create information somehow making their life better.

Software Engineering as a Discipline

Engineering approaches and common engineering principles form an integral part of the theoretical and practical foundations of SE. In conventional engineering, the common approach is to move from abstract to concrete, and the final product is usually the realization of an abstract design

physically. In SE, however, as explained by Yingxu Wang, this approach is reversed. Moving from the physical world to the abstract, the final product is the virtualization and coding of a software design that expresses and represents a real-world problem. As an engineering discipline applying theories, processes, methods, and tools to build high-quality software, SE is concerned with all aspects of software production, from the phases of determining requirements and meeting system specification to maintenance of the system after delivery. SE is the use and establishment of SE principles in order to obtain reliable, measurable, and efficiently working large-scale software with high productivity. Software engineers apply these principles and look for solutions to problems within limited resources and constraints, such as time, scope, and budget.

As defined by the Institute of Electrical and Electronics Engineers, SE is “the application of a systematic, disciplined, quantifiable approach to the development, operation, and maintenance of software” (CAST, n.d.). Therefore, engineering, computer engineering, computer science, mathematics, systems engineering, management, economics, cognitive science, information science, project management, and quality management are among the major related disciplines. Accordingly, software engineers should have the knowledge of material from these disciplines to some extent. This domain knowledge can also be subdivided into knowledge areas such as SE process models and methods, software quality, requirements, design, construction, testing, maintenance, and configuration management processes. An experienced software engineer should have the fundamental knowledge of SE principles, acquire problem-solving skills, know how to govern software projects, implement software processes, choose software development tools and environments, and master computer programming as well as required programming languages.

Software Engineering Process

An SE process, which is the combination of a set of interrelated activities that are functionally coherent and reusable for SE, transforms inputs into outputs using SE tools and techniques. SE processes and activities (planning, design, construction, testing, configuration management, and

maintenance) occur both at the organizational and project levels to ensure that the software product is delivered effectively and efficiently for the benefit of all stakeholders. Therefore, SE methods and the use of structured modeling techniques provide a systematic approach to both problem-solving and software development. Software processes that are used to specify and transform requirements into a deliverable software product are included in the *software development life cycle* (SDLC) and can be linear and iterative, whereas a *software product life cycle* includes an SDLC plus the additional processes of maintenance, support, and evolution.

It is possible to classify software process models as *prescriptive* or *agile* process models. The focus of prescriptive models is the detailed identification, definition, and application of process activities and tasks, while agile models emphasize a more informal and flexible approach to software processes. It is important to note that there is no ideal or single best software process or a set of software processes. Therefore, a process adopted for a specific software project might be considerably different from a process adopted for another software project. The best of SE processes and models have to be selected, adapted, combined, and applied for each project in an organizational context.

SDLC begins with the *software requirement process*, which includes elicitation, analysis, specification, validation, and management of the needs and constraints placed on a software product and its development. The *software design process* consists of architectural and detailed design, which in turn describes how software is organized into components and desired behaviors in sufficient detail. As one of the life cycle stages, the design process produces a description of the software's structure with a set of models and artifacts serving as the basis for its construction. Software design and architecture methods, such as *object-oriented design* and *structured design*, provide a common framework for software engineers. *Software construction process* refers to the creation of working software through a combination of coding, testing, debugging, verification, and integration activities. This stage produces source files, test cases, documentation, and configuration items that have to be managed in a software project. *Software testing* is the

verification process to determine whether a program or module meets different types of expectations and provides the behaviors on a set of test cases. *Configuration management* includes systematical control of the changes to software as set forth in technical documentation, which also aims to ensure the maintenance of integrity and traceability of the software. Finally, *software maintenance* is the modification of existing software while preserving its integrity. It is performed in order to correct faults, implement enhancements, and adapt software to different hardware and software systems or environments.

Software engineers also must understand quality-related concepts, characteristics, and values, and their application to SE processes. Because they are closely interrelated, the activities pertaining to SE process quality, product quality, and software quality management have a direct impact on the quality of the software process and final product. Therefore, one of the primary responsibilities of software engineers and project managers is to balance the sometimes conflicting demands of project scope, time, cost, risk, software process, and product quality.

Theoretical and Transdisciplinary Foundations of Software Engineering

SE has usually been perceived as a part of computer science, providing basic computing theories and programming methodologies. However, the transdisciplinary foundations of SE indicate that it requires not only domain knowledge but also understanding the theoretical essences that have close relationships with other disciplines. Therefore, theoretical and empirical SE explores models, architectures, and methodologies for large-scale software development as well as the nature and mechanisms of software behaviors and the laws behind them. The main problem in SE can be seen in making connections between the abstract world and the physical world. The basic constraints of SE mostly stem from its intangibility, variability, complexity, and human dependency. Therefore, SE theories and methodologies are developed and adopted primarily for dealing with these challenges.

From an evolutionary point of view, SE can be regarded as a young discipline; however, its theoretical foundations incorporate multifaceted

principles, transdisciplinary theories, and the knowledge acquired from both theoretical and empirical studies, as well as industrial practices. For example, SE emerged from computing theory, which is thus one of its most important foundations. The fundamental models in computing can be classified into *program modeling*, *data and object modeling*, *operational modeling*, and *process and resource modeling*. Computer science provides the computational methods, computer architectures and implementations, computing objects and their abstract representations, and programming methodologies.

Mathematics is of course a key means of abstraction and thus constitutes the most general form of human knowledge in science and engineering. For this reason, SE uses it to express basic notions in forming conceptual models; in the design and treatment of architecture; and to define abstract objects, relations, and software behaviors at the highest level of abstraction. Topics such as mathematical logic, set theory, and functions and relations are essential means for modeling software architectures and behaviors. Regarding the foundations of systems science, it is also seen that the concept of systems is applied in many disciplines of science and society, and that a system may be classified into any of a variety of categories depending on its key characteristics and components. Given their highly complex and abstract nature, software systems commonly adopt system theory in their life cycle. Thus, ISO/IEC 15288 provides a process model that accepts large-scale software development as part of software systems to help in dealing with assorted problems and complexities in SE. Because system engineering is concerned with all aspects of systems development that may include process, hardware, and software, SE may be viewed as part of this more general and abstract process.

Information is the product of natural or machine intelligence, and *information science* studies the nature of information and the ways of its processing and transformation. Accordingly, the main function of languages is widely viewed as that of communicating information and expressing abstract human thoughts and behaviors. In the same context, the discipline of linguistics studies natural languages, which are oral, written, or symbolic systems for communication, thought, and self-expression. Therefore, software can be seen as

a type of behavioral and instructive information about architectural and behavioral aspects of a software system. Programming languages describe and specify this computing and instructive information about the architectural and behavioral aspects of the software system.

One discipline that has strong ties with SE is *cognitive science*, which consists of multiple research disciplines. Cognitive science studies mental processes; it explores how information is represented, processed, and transformed within the brain and in computing systems while addressing the constraints on cognitive processing of information. Software is initially generated, represented, and cognitively processed in the long-term and working memory of the brain before it can be transferred to a computer. Indeed, both problem-solving and SE have much in common in that both require high-order cognitive skills and engage a variety of cognitive components. Therefore, acquiring computer programming skills and development of large-scale software systems are based on fundamental cognitive processes. *Information processing theory* and *cognitive load theory* are examples of theories in this knowledge domain and are also extensively used in the research studies of various disciplines.

Another example for the foundational disciplines is that of *management science*, which primarily studies how an organization may be operated effectively and efficiently within given internal and external constraints and in different environments. It involves organizational theories, decision theories, operational theories, quality theories, and strategic planning. Management is a process whose main functions—planning, organizing, and controlling—are instrumental to achieve goals that may not be possible for individuals acting alone. When tracing the history of SE, it can be seen that many of its important concepts, such as requirement analysis, design testing, and quality control, were borrowed or adopted from the methods and practices developed in management science and in other engineering disciplines. Therefore, in addition to computer programming and technical aspects of software development, SE also deals with the issues of organization and management infrastructures.

Theory Use and Development in Software Engineering

Theories are commonly viewed as a coherent set of tested propositions, which are generally regarded as correct, and able to predict or explain facts or phenomena in SE. A theory should have empirical foundations and be grounded in the systematic collection of empirical evidence, thereby maximizing its potential use by practitioners and researchers. Hence, an SE theory provides a conceptual framework for explaining observed phenomena and aids in understanding the basic concepts and underlying mechanisms of software systems and their behaviors. Because SE is an applied discipline and each SE case is unique, a theory may need local adaptations, and it is expected to be relevant, formalized, and ultimately useful for the software industry.

When supporting research studies, an SE theory helps engineers to develop and combine research programs and facilitates communication of knowledge and ideas. Within the industry, it may provide software decision makers with required input regarding the selection of a method, tool, or technology for a software project. There may be three modes of theory used in SE: using theories from other disciplines as they are, adapting theories generated in other disciplines to SE, and generating theories from scratch in SE discipline.

According to Shirley Gregor and to Jo Erskine Hannay and colleagues, there are also five types of theories that may be adapted to an SE context: (1) “analysis” theories, which include classifications, taxonomies, ontologies, and describes object of a study and “what is”; (2) “explanation” theories, which explain why something happens or why a phenomenon occurs; (3) “prediction” theories, used to predict what would happen using probabilistic and mathematical models; (4) “explanation and prediction” theories, which are empirically based; and (5) “design and action” theories, which are usually prescriptive and which describe how to do things in an SE process.

Dag I. K. Sjøberg and colleagues suggest that four main parts, such as (a) constructs, (b) propositions, (c) explanations, and (d) scope, may comprise the structure of an SE theory. The constructs are the basic components in which an SE theory is expressed and to which this theory provides a

prediction or description. Propositions are formed by the relationships indicating how the constructs interact. The explanations, which are also experimental observations of propositions, are logical reasons showing why the propositions are as specified. The circumstances under which the theory is assumed to be applicable define the scope of an SE theory. Thus, constructs and the relationships between constructs form the building blocks of SE theories, and they should be derived from or associated with four archetype classes: (1) *actor*, (2) *technology*, (3) *activity*, and (4) *software system*. The subclasses *industry*, *organization*, *team*, *individual*, and *project* may extend from the parent class *actor*. A programming language, tool, technique, method, model, and process can be the subclasses of class *technology*. Planning, analyzing, designing, developing, and modifying a software system are the subclasses of class *activity*. Finally, application domain and type of software and project subclasses may belong to the parent class *software system*. These classes and subclasses, together with condition statements, define the scope of an SE theory and for whom, where, and when the theory applies.

SE requires both empirical and theoretical research. Empirical SE studies explore, predict, and try to explain the investigated cause–effect relationships between constructs of a theory and find out what types of SE constructs, which are also derived from the archetype classes, should be used in what situations and circumstances. An SE experiment is, therefore, the primary research method directly to make comparisons and to observe the effects of measures taken to improve an SE process. The research approaches for empirical studies should be based on quantitative, qualitative, or mixed research paradigms, which may also use experiment, case study, benchmarking, and standardization methodologies with statistical analysis techniques. According to Hannay and colleagues, the roles that a theory would play in SE experiments include the following: (1) The design of an experiment for the hypotheses may be justified by a theory; (2) a theory may be used to explain observations on the cause–effect relationships after an experiment; (3) a theory may be tested directly with an experiment when additional justification is necessary; (4) an existing theory may be refined and enhanced and then it needs to be tested; (5) a theory may involve and

provide structural elements as a basis for the use of another theory.

Conclusion

Historically, language-centered computer programming has been dominant in SE. Technical innovations in SE have served from time to time as a major driving force for SE trends and practices. However, certain fundamental problems remain, and some authors have claimed that the issues may be regarded as theoretical and not only practical ones. This may be supported by studies reviewing theory use in empirical SE and reporting the lack of explicit and/or relevant theory use in SE. Indeed, there is evidence that an awareness of the theoretical problems and the importance of theory use in SE does exist. However, as noted by Hannay and associates, the majority of studies appear to provide post hoc explanations of the results, or they justify research questions rather than exemplify a theory-driven research study in SE. Therefore, there have also been attempts to indicate that SE may need more general, discipline-specific, or unified SE theories as in some other disciplines.

SOUNDNESS

A deductive argument is valid if, and only if, it is of a form that makes it impossible for the premises to be true and the conclusion to be false. If this is not the case, then the argument is invalid. A deductive argument is sound if, and only if, it is valid and all the premises are in fact true. If not, the deductive argument is considered unsound. This entry discusses the concept of soundness, which is perhaps the single most important concept in logic.

A sound argument is guaranteed to preserve truth. Other fields can decide which premises are true, then logic can guarantee that when true premises are used in a sound argument the conclusion must also be true. Looked at this way, only two things are worth discussing: logic, which tells us which arguments preserve truth, and everything else, which tells us which premises are worth arguing from.

Soundness in Deductive Logic

A deductive argument is an argument that is intended to be deductively valid, that is, one that provides a guarantee that the conclusion is true on the basis that the argument's premises are true. In a deductive argument, the premises must provide strong support for the conclusion, such strong

support in fact that if they are true, it will be impossible for the conclusion to be false.

This is in comparison to an *inductive* argument, which is an argument that seeks to show that its conclusion is probably, albeit not necessarily, true. An inductive argument claims only that if the premises are true, then the conclusion is likely to be true, but not necessarily so.

Deductive arguments are generally expressed using terms such as *therefore*, or *it follows that*, or *it must follow that*, and so on. Inductive arguments are introduced using terms such as *it is probable that*, or *it is likely that*, and so on.

The following are examples of deductive arguments where it is apparent that the argument aims to show that the conclusion is true if the premises are true. The first argument is valid, while the second is invalid:

1. All cats are mammals.
2. All mammals have warm blood.
3. It must therefore be the case that all cats have warm blood.

1. All cats are mammals.
2. All human beings are mammals.
3. It must therefore be the case that all cats are human beings.

The difference between these two arguments is that the first argument involves good reasoning and the second, poor reasoning. The first argument is a valid argument, and the second is invalid. What is sometimes confusing is that arguments can be valid even when they have false premises and false conclusions. For example:

1. All pilots are Buddhists.
2. All Buddhists are millionaires.
3. It must be the case that all pilots are millionaires.

The premises in the above argument are false, and even though the conclusion is false too, the argument is a valid one. That is because if the premises had been true, the conclusion would have been true as well. So, the argument is in line with the definition of a valid argument. Thus, true premises are not required to achieve validity. Logically,

valid does not entail *true*. An argument can be valid so long as if the premises are true then the conclusion must be true. An argument is considered valid if the premises and the conclusion are related in the right way, and we can recognize that even if one of the premises is in fact false that if were true the conclusion would have been true, too.

Despite an argument being valid, however, we would also like for it to be true. If an argument is valid, and additionally it is the case that the premises are true, then we have what is known as a valid argument which is sound. Validity is concerned with the structure of an argument, while soundness is the substance of the argument.

A sound argument has the following properties:

1. That all the premises are true.
2. That it is valid.

Truth, which means a correspondence with reality, is our ultimate goal when we are reasoning. Soundness is the overriding aim of deductive reasoning, not just validity. If our deductive argument is both sound and valid, we have a best-case scenario. This argument is both valid and sound:

1. All cats are mammals.
2. All mammals are animals.
3. Therefore, it must be the case that all cats are animals.

In the previous argument, where we discussed pilots and Buddhists, the argument was valid but unsound. It's worth pointing out that both invalid and valid but unsound arguments can entail true conclusions. We cannot reject an argument's conclusion by simply discovering that the given argument for the conclusion is flawed.

Logical Form

Whether the premises for an argument are true or not depends on the specific content. Most logicians, however, understand the validity or invalidity of an argument as being determined solely by its logical form. The logical form of an argument is what is left behind when we abstract

away from the specific content in the premises and the conclusion (i.e., words that name things, properties of things and their relations) to leave just those elements common to discourse and reasoning. This discourse and reasoning can be about any subject matter, for example, words such as *and*, *all*, *some*, *not*, and so on. The logical form of an argument is represented by replacing specific word content with letters used as *placeholders*, or variables.

Consider the following two examples:

1. All cats are mammals.
 2. No mammals are creatures with scales.
 3. It must be the case that no cats are creatures with scales.
-
1. All orangutans are zebras.
 2. No zebras are animals.
 3. It must be the case that no orangutans are animals.

These arguments have the same logical form:

1. All A are B.
2. No B are C.
3. It must be the case that No A are C.

Arguments with this form are valid, and because they have this form, the examples just shown are valid. However, the first argument is sound, and the second argument is unsound since its premises are false. In the following:

1. All footballs are round.
 2. The Earth is round.
 3. It must be the case that the Earth is a football.
-
1. All popes live in the Vatican.
 2. John Paul II lives in the Vatican.
 3. It must be the case that John Paul II is a pope.

These arguments also have the same form as:

1. All A's are F.
2. X is F.
3. It must be the case that X is an A.

These types of arguments are invalid, and we can easily see this in the first example. The second

example might appear like a good argument since the premises and the conclusion are true, but in fact the conclusion's truth is not guaranteed by the truth of the premise. It might have been the case that the premises were true and the conclusion false. That makes this argument invalid and entails that the argument is also unsound. Although most contemporary logicians accept that logical validity is determined entirely by form, there is some disagreement. Consider the following:

1. My table is round. Therefore, it is not square-shaped.
2. Jules is a bachelor. Therefore, he is single.

These arguments appear to have the form
X is F, therefore X is not G.

Arguments of this form are not as a rule valid. However, it seems intuitively the case that it must be impossible for the premises to be true without the conclusion being true too.

Logicians would respond to this puzzle in any of a number of ways. Some could insist, controversially, that these arguments actually contain premises that are implicit, for example, "Nothing can be both round and square shaped." Or "All bachelors are single," which, while they are in themselves necessary truths, also play a role in the form of the arguments. It could also be proposed that although (notwithstanding the addition of the additional premise) there is a necessary connection between premise and conclusion, the type of necessity involved is not a *logical* necessity, which means that the argument in the simple form cannot be considered logically valid. Finally, and especially when we look at the second example, a logician might suggest that because a *bachelor* is defined as an unmarried male, the true logical form of the argument is the following universally valid form:

X is F and not G and H.

Therefore, X is not G.

It is not as easy as first thought to determine the logical form of a statement. Statements with apparently identical grammatical form can have different logical form. For example:

Nigel is a ferocious lion.

David is a lame duck.

The two statements might look the same, but only one (1) has the form X is an A that is F. From this, we can infer (validly) that Nigel is a lion. We cannot deduce that David is a lame duck in (2). This same sentence can be used in other ways and in other contexts, for example:

The prince and princess are visiting dignitaries.

At first sight, it isn't clear what the logical form of this sentence is, whether there are dignitaries that the prince and princess are visiting in which case the sentence takes the same logical form as "The prince and princess are playing guitars," or whether the prince and princess are themselves dignitaries. In that case, the sentence would have the same logical form as "The prince and princess are quivering cowards."

Depending on the form the sentence is thought to take, the inferences are either valid or invalid.

Consider the following:

The prince and princess are visiting dignitaries.

Visiting dignitaries is tiresome.

Therefore, the prince and princess are doing something tiresome.

This statement can only be considered valid if the statement is given in the first reading.

Soundness in Formal or Symbolic Logic

Because it's so difficult to identify the logical form of an argument, along with the potential to deviate from logical form to grammatical form in everyday language, logicians tend to make use of artificial languages in which logical and grammatical form coincide. These artificial languages contain symbols similar to the ones used in mathematics to represent ordinary words such as *all*, *or*, *and*, and so on. This makes it easier to set rules that can determine whether the argument is valid or not. The study of deductive argument forms to ascertain whether they are valid or invalid is termed *formal* or *symbolic logic*.

In order to evaluate a deductive argument, we need first to ask whether the premises support the conclusion by considering the form the argument takes. If they do, the argument is valid. Next, we need to ask whether the premises are

actually true or false. If and only if the argument passes both of these tests can we say with confidence that the argument is sound. If the argument doesn't pass the tests, then it is possible that the conclusion may still be true, notwithstanding the fact that no support for its truth has been provided in the premises.

Soundness and Completeness in Mathematical Logic

The idea that mathematics is logic goes back to the philosopher and mathematician Gottfried Wilhelm Leibniz (1646–1716). But during the 19th century, the basic principles of fundamental mathematical theories were established by Richard Dedekind (1831–1916) and Giuseppe Peano (1858–1932) and the principles of logic by Gottlob Frege (1848–1925).

Soundness is one of the most important properties of mathematical logic, providing the reason for seeing a logical system as desirable. Logical systems are sound if, and only if, every formula to be proven within the system is logically valid with regard to the semantics of the system. In most cases, this necessitates the rules having the property of preserving truth.

Many proofs of soundness are trivial; for example, when we are discussing an axiomatic system, the proof of soundness is simply the validation of the axioms, and that the rules of inference preserve validity, or weaker property of truth. Most axiomatic systems feature the rule of *modus ponens*, which requires only the verification of axioms and a single rule of inference. A soundness theorem for a deductive system expresses that all provable sentences are true: All sentences are provable.

Properties of soundness can be either weak or strong, the former of which is a limited version of the other. Strong soundness entails that any sentence P of the language upon which the deductive system is based that is derived from a set (S) of sentences in that language is also a logical consequence of that set. In other words, any system that makes all members of S true will also make P true. Where S is empty, this is a statement of weak soundness.

In arithmetic, T is arithmetically sound if all theorems of T are actually true about the mathematical integers.

The completeness property is the complement of soundness. The completeness property requires that every validity or truth is provable.

Soundness: If something is provable, it is valid. If $\vdash \phi$ then $\models \phi$.

Completeness: If something is valid, it is provable.

If $\models \phi$ then $\vdash \phi$.

Completeness of first-order logic was established by Austrian-born American mathematician and philosopher Kurt Gödel (1906–1978); however, earlier work by the Norwegian mathematician Thoralf Skolem included some of the earliest results in this area.

Gödel suggested two incompleteness theorems of mathematical logic. These works were important to both mathematical logic and the philosophy of mathematics. They are widely interpreted as disproving Hilbert's system for finding a complete and consistent set of axioms for all mathematics as impossible. According to Gödel, you cannot have a set of axioms that are as follows:

1. Complete, that is, for any ϕ , either $A \models \phi$ or $A \models \neg \phi$.
2. Sound, that is, if $A \models \phi$ then ϕ is true of the natural numbers. (It is not possible to prove, e.g., that every number is prime or that $1 = 2$.)
3. Axiomatizable (i.e., that you can write a program that examines a formula and tells you whether or not it is an axiom).

For every assumption you make about natural numbers, there will be elements that are true but cannot be proven.

Gödel's incompleteness theorems were followed by closely related theorems on the limitations of formal systems, including Alfred Tarski's undefinability theorem, Alonzo Church's proof that David Hilbert's *Entscheidungsproblem* is unsolvable, and Alan Turing's theorem that no algorithm can solve the halting problem.

Together, soundness and completeness imply that all and only validities are provable.

SPECULATION

Viewed purely as a mental operation, *speculation* is performed by way of pragmatic, future-oriented reflection and conjecture which might be based in experience or other empirical evidence but doesn't necessarily have to be. In its classic philosophical sense, *speculation* is concerned with such metaphysical questions as first causes of the universe, whether the soul is immortal; it is a search for ultimate meanings and truths. In popular culture, *speculative* inquiries into such realms as *cryptozoology* and *ancient astronaut hypotheses*, considered pseudo-scientific due to the absence of verifiable data, are often found to be interesting but not credible. (It can be noted that debunkers of theories may themselves be engaging in speculation.)

This entry discusses speculation historically and identifies major theorists, theories and situations related to economic speculation. Game theory, decision theory, and crowdsourcing are described as applications of increasingly sophisticated speculative techniques, with a brief focus on ethical considerations related to certain forms of speculation.

Models of Speculative Reasoning

Despite the heavy emphasis Western cultures place upon logical operations, a high percentage of human decisions are carried out based upon intuition, emotion, experiential knowledge—all of which factor into processes of speculation. Procedures to simplify decision-making in the face of

risk and uncertainty have been developing since the Dark Ages.

When there are multiple options, uncertainty of outcomes produces affective disturbance in proportion to the level of emotional investment in a hoped-for outcome; the more choices, the more emotionally loaded the decision and sense of risk becomes. Difficult outcomes for certain situations that tend to recur in human experience include the *Hobson's choice* (one option, no alternatives: "Take the horse nearest the stable door or walk"); *Morton's fork paradox* (two options which seem opposed have the same, usually unpleasant, end: "If she is a witch, she will float and face execution; if she isn't, she will drown"); *Sophie's choice* (several options, all having undesirable outcomes); *Procrustean bed* (where all options are tied to a single set of arbitrary data which may be violently enforced); and *double-bind situations* (discursively constructed dilemmas framed to preclude any workable response, such as "Are you still lying?").

Attempts to reduce risk and uncertainty in decision-making produced early strategies for more accurate speculation. The Franciscan friar William of Ockham, a 14th-century logician, prescribed that one should apply empirical evidence to theory. If several similar theories are offered, one should select the simplest, that is, one that makes the fewest assumptions. Thus, *Ockham's razor* will shave away extraneous material, leaving the "elegant solution."

The relationship between gambling and risk management is obvious; however, the ability to mathematically speculate upon outcomes was first documented in 1550 when Italian mathematician-physician Girolamo Cardano attempted to calculate the odds of a pair of dice rolling a double-six. In the 17th century, French mathematician-philosopher Blaise Pascal and number theorist Pierre de Fermat also addressed the "problem of points" first posed by the Franciscan monk Luca Pacioli in the late 15th century. The question centers on a hypothetical game of chance which is interrupted with stakes still on the table; the problem is how to divide the pot fairly. Pascal's and Fermat's calculations were foundational for *probability theory*.

In terms of abstract, metaphysical speculation, Pascal's logical reflection focused on the question

of whether God exists. Since the existence of God cannot be determined by reasoning alone, Pascal weighed the benefits accruing from being right against the consequences of being wrong. *Pascal's wager* led him to “decide” to believe in God.

Development of Mathematical Models

The realization that outcomes of apparently random or chance events might mathematically be forecast led to development of increasingly sophisticated mathematical models oriented toward predictive efficacy. The history of the commercial insurance industry, for example, emerged from efforts to manage risk and uncertainty associated with maritime enterprises. Galileo's development of the telescope in 1609 enhanced not only metaphysical speculation about the cosmos but also economic speculation about when (and whether) merchant ships would arrive in port. In the City of London, dissemination of shipping news in Edward Lloyd's coffee house in 1638 evolved into the global insurance corporation Lloyd's of London.

Inspired by Newton's *Principia*, Abraham de Moivre (1677–1754) published *The Doctrine of Chance* in 1718, wherein he applied principles of statistics and probability to games of chance such as “the gambler's ruin.” His ideas of *binomial distribution* provided grounding for the great mathematician Carl Friedrich Gauss's (1777–1855) theorem of *Gaussian distribution, function, and error curve* (the *bell curve*). De Moivre's study of mortality statistics provided a foundation for the *theory of annuities* and actuarial tables used in the life insurance industry. Pierre-Simon Marquis de Laplace (1749–1827) extended probability theory into seminal models of statistics. The deMoivre–Laplace *central limit theorem* was a key advance in probability theory; it posits that the sum or average of a large number of independent but identically distributed variables will approximate a “normal” distribution.

British statistician Thomas Bayes's (1701–1761) major contribution to probability studies is his inductive approach to *probability inference*, based upon outcomes of prior trials. His *Essay Towards Solving a Problem in the Doctrine of Chances* (1764) presented conclusions that were both highly influential and highly debatable. Bayes's

Theorem is a model of *conditional probability* which factors in the interplay of subjective degree of belief and available evidence.

The polymath Sir Francis Galton (1822–1911) used statistics and probability models in his studies of intelligence and developments in psychometrics that included definitions of “the normal curve” and *regression toward the mean* when extreme random events are remeasured. First germane to his study of genetics, the regression concept has been applied (and also misapplied) in economic analysis and stock forecasting, as well as in experimental design, weather forecasting, and prediction of batting averages.

Stochastic processes are those that are “subject to chance” rather than deterministic, as with trials occurring within a framework where initial conditions and, therefore, outcomes are the same. Stochastic models and techniques have been applied to learning and manufacturing processes, biological phenomena, population questions, and even in musical composition. In 1900, French doctoral student Louis Bachelier (1870–1946) successfully defended a unique dissertation at the Sorbonne. His thesis developed a mathematical approach to financial speculation with a seminal application of stochastic analysis. His *theory of speculation* incorporated the notion of *Brownian motion* that would be more fully elucidated by Albert Einstein in a groundbreaking paper published 5 years later. Bachelier's work laid the groundwork for stochastic calculus; the date of his dissertation defense, March 29, 1900, has been called *the birthdate of mathematical finance*.

Innovations in speculation science near the turn of the century incorporated the scholarship of economists Irving Fisher (1867–1947), whose 1907 enunciation of a formula for *net present value* (one discounts cash flow at a rate congruent with the level of risk involved) is a boon to valuation of assets, as well as the theories of Frank Knight (1885–1972). An influential founding member of the Chicago school of economics, Knight was the first to attempt to explain the distinction between *risk* (where outcomes are unknown but measurable, being governed by probabilities) and *uncertainty* (which involves unmeasurable unpredictability). Broadly similar to this concept of *Knightian uncertainty* Nicholas Nassim Kaleb's (1960–) *black swan theory*

discusses the impact of unexpected, improbable events that seem, in hindsight, to have been inevitable.

Fischer Black's (1938–1995) and Myron Scholes's (1941–) work in the growing field of financial economics exerted a strong impact on risk management. The *Black–Scholes pricing model*, published in 1973, is very close to the *Bachelier model*. Robert Merton (1910–2003) did similar work in evaluation of stock options. Scholes and Merton were awarded the Nobel Prize in Economics in 1997. (Because the prize is not presented posthumously, Fischer Black was not eligible.)

The interdisciplinary scholar Roy Radner (1927–) said in 1979, “When traders come to a market with different information about the items to be traded, the resulting market prices may reveal to some traders something about the information available to other traders” (1979, p. 655). This initial information taken collectively will establish an equilibrium of expectations that can ultimately affect prices and trading, and this is the basis of the *rational expectations equilibrium model*. Similarly to the *observer effect* correlated with *Heisenberg's uncertainty principle* in quantum physics, information inputs and expectations of actors can decrease potential exactitude, increase indeterminacy, and must be factored into calculations.

Development of Nonrational Models

The aim of speculation is to manage uncertainty about possible outcomes by weighing probabilities. In 1738, Daniel Bernoulli's reflection on random events based upon the individual's emotional orientation to a proposed outcome laid the groundwork for *risk science*.

Centuries later, cognitive psychologists Amos Tversky and Daniel Kahneman (1974) elaborated on the affective dimension of decision-making—or gut feelings—when they investigated how people actually make decisions in risk situations. They found that the use of three particular heuristic sets to make decisions under uncertainty conditions are predictable. These are *representativeness*, *availability of previous instances*, and *anchoring* (overreliance upon the conceptual starting point)

and *adjustment*. Because of the irrational nature of such an approach, these mental shortcuts will also lead to predictable cognitive biases. Their research demonstrating the tendency of human judgments to follow intuitive, nonrational processes in decision-making rather than to conform to mathematical models was foundational in the field of *behavioral economics*.

Tversky and Kahneman's *prospect theory* delineates the effect that the framing of choices and potential outcomes conceived of terms of “possible gains” as opposed to “losses” will have on the person's decision, with the “loss” frame being weighted more heavily. The theory, developed over three decades, illustrated the difference between subjective perception of probabilities and mathematical probabilities which leads to illogical choices in the face of risk and uncertainty.

Economic Speculation: Bubbles and Crashes

Banks were established during the Roman Empire, but banks could not manage the totality of financial transactions, resulting in the affiliated trade of moneylender. The first stock-traders were itinerant European moneylenders from about the late Middle Ages. A stock exchange existed in Antwerp, Belgium, as early as 1531. The East India companies began issuing shares in the early 1600s in an effort to mitigate the risk and high losses of maritime trade. The London stock exchange began in coffee houses in 1698 (as noted earlier concerning the founding of Lloyd's of London) and is one of the oldest. The New York stock exchange, the world's largest, was established in 1792. Edward A. Calahan's invention of the stock-ticker in 1867 revolutionized the buying and selling of stocks and stimulated stock speculation.

If one arranges arbitrage (buying a commodity at a certain price and immediately re-selling it at a higher price), investment, and gambling along a spectrum, speculation will usually fall somewhere between investment and gambling, although that is not a bright line. Philip Carret in *The Art of Speculation* (1927/2007) described the difference between a “speculator” and an “investor” in this way:

The man who bought United States Steel at 60 in 1915 in anticipation of selling at a profit is a speculator . . . On the other hand, the gentleman who bought American Telephone at 95 in 1921 to enjoy the dividend return of better than 8% is an investor. (p. 5)

Stock-trading is an intrinsically speculative activity, with speculation often leading to overspeculation and booms, bubbles, and crashes.

The stock market crash of 1929 was attributed to overspeculating “on margin” (simply put, financing primarily through credit). In 1936, economist John Maynard Keynes, himself a successful stock-speculator, wrote: “Speculators may do no harm as bubbles on a steady stream of enterprise. But the situation is serious when enterprise becomes the bubble on a whirlpool of speculation.” The “2008 bubble” which burst globally was also blamed on exuberant overexpansion of speculation in oil, food prices, real estate, and other commodities.

Irrational investor speculation led to the *Dutch tulip craze* in 1637, one of the first economic bubbles on record. An account in the April 1876 issue of *Harper's New Monthly Magazine* described the Dutch people's hysteria for the flower having grown so extreme that a single bulb sold for “\$1840, a new carriage, two gray horses, and a complete suit of harness.” Regarding the *bitcoin craze* of 2013, Nout Wellink, former president of the Dutch Central Bank, condemns this as pure speculation, comparing it to the 17th century tulip craze, says, “At least then you got a tulip [at the end], now you get nothing” (quoted in *The Hill*, n.p.).

Game Theory and Decision Theory

In 1944, John von Neumann and Oskar Morgenstern established a mathematical approach to decision-making which assumes that choices will be made by rational, consistent actors. Herbert Simon debunked this in presenting his theory of *bounded rationality*. Under this model, the absence of resources required for fully rational (*optimizing*) decisions requires that intuition, experience, and logic work together to arrive at “good enough” (*satisficing*) decisions. Even so, several

models of decision-making hypothesize a certain level of rationality and have found some application in college and university curricula for modeling and teaching critical thinking.

Speculation framed as rational and strategic is the basis of *game theory*. The three ingredients for a game generally are players, actions or strategies each can take, and each player's preferences. The objective is to logically and objectively determine choices that a player should make to obtain the best possible outcome. Game scenarios can be developed across a variety of human situations, including disputes and negotiations. The scenarios are structured in such a way to maximize the interdependence and interaction of the players, who may perceive that their goals are incompatible, literally the recipe for *conflict*. Game outcomes may be *zero sum*, *positive sum*, or *negative sum*.

In a zero-sum game such as Matching Pennies, each player's gain equals others' losses, so there is no cumulative net gain or loss, and if a party benefits, it's at the expense of the others. In a positive-sum game, the cumulative total is greater than zero, indicating that all parties have benefited in some way in a win-win scenario. A negative-sum game culminates in a lose-lose outcome where all players suffer loss, with the cumulative total being a negative number.

Games can be cooperative or noncooperative. But even in noncooperative games, there is a point of equilibrium where none of the players would benefit if they diverged from an agreed-upon course of action. John Forbes Nash (1928–2015), whose life was the basis for the film *A Beautiful Mind*, was awarded the Nobel Prize in Economics for developing this insight into what has become known as the *Nash equilibrium theory*.

Examples of games built around hypothetical situations include the Prisoner's Dilemma, the Bubble Game, and the Kobayashi Maru game based on the *Star Trek* series. Real-world situations categorized as negative-sum games include war and genocide, arms races, bee colony collapse disorder, and similar environmental situations. Positive-sum games that occur in life could include surplus trade agreements, microloans, corporate joint ventures, and integrative bargaining within organizations.

American ecologist Garrett Hardin (1915–2003) said, “Each man is locked into a system that compels him to increase his herd without limit—in a world that is limited” (1968, p. 1244). Hardin’s *tragedy of the commons* thesis states that individuals will act rationally in their own behalf to maximize personal gain, but this is irrational in terms of long-term outcomes and the common good when they damage or deplete a common resource. A number of game theory scenarios are predicated upon this thesis. One true instance is speculation involving wildlife commodities such as ivory, black rhino horn, and similar animal parts; as the creature moves closer to extinction, the body part increases in value.

Decision theory or *decision science* or *rational choice theory* is related to game theory and is concerned with the ways that people, in a nonrandom way, freely choose among options available to them. Decision science is rooted in scholarship and theory but is generally aimed more toward pragmatic application in economics, statistics, psychology, the social sciences, and especially marketing and strategic communication. Decision theories tend to delineate how people actually do arrive at the decisions they make rather than the underlying processes that, ideally, they should follow.

Speculation as Forecasting

A relationship between crowd psychology and speculation and the impact of suggestion and “herd mentality” on economic and sociopolitical situations has been well documented. But rather than solely negative outcomes whereby crowds can act violently and do damage, recent experiments have demonstrated that crowds possess uncommon wisdom as well. This is beneficial in institutional decision-making, instrumental in public policy formulation, and directive for market research. Combining aspects of game theory and decision science, *social forecasting* or *crowdsourcing* draws on “the wisdom of crowds” and *the law of large numbers*; answers are expressed numerically with calculations facilitated by computer applications.

One such forecasting endeavor is The Good Judgment Project, now in its fourth year of tournaments that ask nonexpert participants to predict

outcomes of world events. University of Pennsylvania psychologist Phil Tetlock (1954–), cofounder of the project with Barbara Mellers and Don Moore, had studied political forecasters for two decades and became interested in how they achieved success or failure. Tetlock identified two categories of predictors. “Hedgehogs” are invested in and very knowledgeable about a “single central vision”—they have bought into a “grand theory” and are “true believers.” “Foxes,” on the other hand, have many interests, are humble about their level of knowledge, and intellectually adaptable. Foxes are better at prediction. Findings from the first three tournaments indicate that ordinary citizens, with a little training in probability and prediction, consistently outperform such professionals as the members of the U.S. Central Intelligence Agency.

Data mining, predictive analytics, and social forecasting are used to understand alternatives, recognize and resolve cognitive biases, and bolster non-data-based decision-making practices. Harvard’s interdisciplinary Decision Science Laboratory serves a pool of investigators, assisting in experiment design and coding, recruiting of subjects, analysis of findings, and training of student-investigators in studies focusing on nonrational elements of decision-making. Similarly, Columbia Business School’s Center for Decision Sciences facilitates research and understanding on consumer behavior, the implications of decision making on public policy, and the neurological underpinnings of judgment and decision-making.

STATISTICAL INFERENCE, BAYESIAN

Bayesian statistical inference is based on the subjective interpretation of probability. Uncertainty about an unknown quantity or a parameter of interest is expressed by a probability distribution that represents the agent's subjective degrees of belief. Bayesian Conditionalization and Bayes's Theorem describe how learning data changes this (prior) probability distribution into a posterior probability distribution. Standard procedures of statistical inference, such as point and interval estimation, can be formulated as functions of the posterior distribution. Hypothesis tests are

evaluated by means of the Bayes factor—that is, the degree to which the odds for either hypothesis have changed in the light of the data. All in all, Bayesian statistical inference has high flexibility and can be applied to a large number of important statistical problems, such as generalized linear regression, model selection, and sequential analysis.

Basic Principles

It is well known that in classical, frequentist inference we cannot assign a probability that an unknown parameter μ takes a particular value or falls inside a particular interval. We can only talk about the probability of observing certain types of data, given a particular value of that parameter, and interpret this probability as a relative frequency. Bayesians break with this rule: They use (subjective) probabilities for expressing all kinds of statistical uncertainties, including the probability of an unknown parameter being in a particular interval.

Suppose we test a null hypothesis $H_0: \mu \leq 0$ against an alternative hypothesis $H_1: \mu > 0$. A Bayesian assigns a prior probability distribution over μ (e.g., in the form of a probability density function). Suppose we observe some evidence E , for example, values of an observable whose probability distribution depends on the value of μ . The Bayesian calculates the posterior probability of H_0 and H_1 as the conditional probability of these hypotheses, given the observed evidence: $p_{\text{new}}(H_0) = p(H_0|E)$ and $p_{\text{new}}(H_1) = p(H_1|E)$. This updating principle is called *Bayesian Conditionalization*.

For calculating these conditional probabilities, the Bayesian statistician makes use of *Bayes's Theorem*:

$$p(H_0 | E) = p(H_0) \frac{p(E | H_0)}{p(E)}$$

$$p(H_1 | E) = p(H_1) \frac{p(E | H_1)}{p(E)}$$

It has been argued that the posterior distribution of an unknown parameter is the real target of

statistical inference, and Bayesian inference is the only school of statistics that can deliver it. Moreover, the posterior distribution can be used in a decision-theoretic calculus for inference and decision-making, in agreement with *expected utility theory*. Since the likelihoods $p(E|H_0)$ and $p(E|H_1)$ are based on the sampling distribution of the observed data under the competing hypotheses, the posterior distribution is the product of a distinctly subjective element—the prior distribution—and a more objective element, represented by the likelihoods.

Bayesian statistical inference has some important advantages over frequentist inference. Most importantly, the posterior takes the base rate of an event or hypothesis into account (i.e., $p(H_0)$ and $p(H_1)$). Therefore, it avoids common fallacies in frequentist statistics, such as base rate neglect or the inverse probability fallacy (i.e., inferring from $p(E|H)$ to $p(H|E)$). Bayesians also dispense with p values and do not need to bother about their correct interpretation.

Similar to frequentist tests, Bayesian statistical methods produce point values of parameter estimates (e.g., regression coefficients). Uncertainty around these estimates is quantified in terms of a *credible interval*. Point estimate and credible interval are the central tendency (mean, median, or mode) of the posterior distribution and its 95 central percentiles or 95% highest density interval, respectively. Unlike frequentist confidence intervals, credible intervals have a natural and intuitive interpretation: a 95% credible interval of parameter μ is an interval I in the parameter space such that $p(\mu \in I) = 95\%$. Credible intervals are also at the basis of modern Bayesian inference techniques, such as regions of highest posterior density.

To wrap up, the main ideas of Bayesian inference can be summarized by the following three principles:

- the representation of subjective degrees of belief in terms of probabilities;
- the use of Bayesian Conditionalization and Bayes's Theorem for updating subjective degrees of belief;
- the use of the posterior probability distribution for estimating parameter values, accepting hypotheses and making decisions.

Hypothesis Tests and Bayes Factors

The prior and posterior distributions give clear answers to the questions of what we should *believe* and what we should *do* or *decide*. However, they do not quantify the amount of statistical *evidence* for either hypothesis, as for example p values do in the context of frequentist inference. That is, they do not state whether the evidence favors H_1 over H_0 or vice versa.

Within the Bayesian framework, hypothesis tests are generally based on *Bayes factors*. They are defined as the ratio of posterior and prior odds and describe by how much the evidence E shifts the posterior distribution from the null hypothesis H_0 to the alternative H_1 :

$$B_{10}(E) = \frac{p(H_1|E)}{p(H_0|E)} / \frac{p(H_1)}{p(H_0)}$$

Alternatively, one can calculate Bayes factors as the likelihood ratio between the two competing hypotheses:

$$B_{10}(E) := \frac{p(E|H_1)}{p(E|H_0)}$$

In this reading, the Bayes factor expresses how much more expected the evidence is under H_1 than under H_0 —or in other words, how much it discriminates H_1 from H_0 . For instance, in the case of a t test or regression, there is some evidence in favor of (against) group difference or the inclusion

Table 1 Interpretation of Bayes Factors as Statistical Evidence for a Hypothesis

Bayes Factor BF_{10}	Interpretation
>100	Extreme evidence for H_1
30–100	Very strong evidence for H_1
10–30	Strong evidence for H_1
3–10	Moderate evidence for H_1
1–3	Anecdotal evidence for H_1
1	No evidence for either hypothesis
1/3–1	Anecdotal evidence for H_0
1/3–1/10	Moderate evidence for H_0
1/10–1/30	Strong evidence for H_0
1/30–1/100	Very strong evidence for H_0
<1/100	Extreme evidence for H_0

of a coefficient in a model when the probability of the observed data is higher (lower) for the model that allows group difference or includes the coefficient with respect to the model with equal groups or without the coefficient; $BF_{10} > 1$ ($BF_{10} < 1$). A conventional interpretation of Bayes factors is provided in Table 1.

An important feature of Bayes factors is that they can express evidence for the null hypothesis—something that is impossible in frequentist inference where evidence either speaks against the null hypothesis or is inconclusive. By being able to quantify the degree of support for the null hypothesis, Bayesian statistics makes a contribution to fighting the file drawer effect: That is, *nonsignificant results* have a hard time to be published in scientific journals. The impossibility of distinguishing between inconclusive results and results that support the null hypothesis in frequentist statistics contributes to this effect since evidence in favor of the null is systematically suppressed. Bayesian statistics, by contrast, allows to confirm theoretically important null hypotheses. Therefore, it is less susceptible to the file drawer effect and contributes indirectly to combatting the replication crisis.

Challenges

Bayesian statistics are often called “too subjective for science.” The idea is that the use of subjective degrees of belief in inference is at odds with the neutrality and impartiality of scientific reasoning, where one should “let the data speak for themselves.” Think, for example, of a regulatory agency that needs to decide on the admission of a drug or vaccine against COVID-19. Certainly it would not be impressed by a probability distribution that is mostly grounded on the subjective degrees of belief of the experimenters (who usually have a conflict of interest with respect to the study results). This is often called the *problem of subjectivity* or the *problem of the prior*.

Priors used in statistical analyses can roughly be categorized in three groups. Subjective priors embody the subjective beliefs and/or prior knowledge of the researcher, for instance a normal distribution that represents the expected value of a certain parameter and the uncertainty around it. Default priors or objective priors are distributions

that satisfy certain general desiderata instead of particular beliefs or prior knowledge the researcher might have. Empirical priors are distributions based on a (certain number of) small subsample(s) of the data to be analyzed.

It is the prior, in any form, that lies at the root of the “too subjective for science” criticism. The responses are twofold: Some Bayesians defer to default or objective priors for inference, while others defend the use of properly subjective priors as scientifically sound. After all, the subjectivity inherent in the specification of priors is explicit, allows others to substitute their own priors, and affords robustness analyses across priors instantiating different prior beliefs. In short, unlike many other decisions made by researchers during the course of an experiment, the subjectivity introduced by the prior in Bayesian statistical analyses is open to inspection and evaluation. Finally, it has been pointed out that subjectivity is inherent to any school of statistical inference and that similar objections can also be raised against the frequentist paradigm.

Applications

Bayesian statistics encompasses counterparts to all standard statistical tests (t test, ANOVA, regression, etc.) and advanced statistical modeling methods (mixed models, hierarchical models, structural equation models, etc.). Software packages such as SPSS and Stata offer Bayesian statistical analyses, in addition to classical/frequentist analyses. Furthermore, there is free-to-use software dedicated to Bayesian statistics, such as the programs MCSim, OpenBUGS, and JAGS, the probabilistic programming language Stan, R packages such as LaplacesDemon, and Python packages such as ArviZ and PyMC3. Finally, there is the free and open-source graphic user interface software package JASP that offers both frequentist and Bayesian analyses, both standard and advanced.

Bayesian statistical inference has several additional advantages, especially when conducted with Bayes factors:

Automatic parsimony. As the prior probability of a hypothesis is distributed across parameters and parameter values (i.e., prior distribution), the more complex a model is (i.e., more parameters and range of values), the more the prior density is

spread out. For the Bayes factor, the likelihood of the hypothesis is marginalized over its parameter, which decreases rapidly when parameters and parameter values are included that do not match the data.

Comparing non-nested hypotheses. Because only the likelihoods of hypotheses are considered for the Bayes factor, no distinction is made between nested and non-nested models. This allows, for instance, the evaluation of order-constrained hypotheses such as $H_1: \mu > 0$ versus $H_2: \mu < 0$.

Sequential analysis. Bayesian hypothesis does not require special corrections for sequential data collection and analysis. The symmetry of the Bayes factor and its sole reliance on likelihoods make the rules of data collection and optional stopping irrelevant to data interpretation. Thus, one can monitor evidence as it accumulates (e.g., for or against H_0) without worrying about the stopping rule. This feature of Bayesian inference is also contentious since according to critics, it licenses reasoning to a foregone conclusion and neglects the (preexperimental) error probabilities of an inference.

Incorporation of existing knowledge. The inclusion of a prior in Bayesian analysis allows the incorporation of existing knowledge, mimicking learning as we know it. Existing knowledge about a phenomenon (e.g., efficacy of a drug) can be captured in a prior and thus contribute to the analysis. Consequently, the resulting posterior can inform the prior distribution for the next experiment. As Dennis Lindley put it, “today’s posterior is tomorrow’s prior.”

Flexible research planning. While the Bayesian framework is not concerned with power analysis in the frequentist sense, it does afford the research planning that power analyses provide. Monte Carlo simulations allow us to draw random samples across scenarios (e.g., where H_0/H_1 is true), priors, sample sizes, and decision boundaries (e.g., $BF_{10} > 10$) to investigate the percentage of samples in which a confirmatory decision is reached for a given statistical test. Conversely, we can determine the necessary sample size for a given statistical test, hypothesis, prior, decision boundary, and probability for reaching this decision boundary (e.g., obtaining a $BF_{10} > 10$ with a probability of .8). Such Bayes factor design

analysis can be used as easily for sequential designs as for fixed sample size designs.

STATISTICAL INFERENCE, FREQUENTIST

Probability theory, a branch of mathematics, provides the foundation and the overarching framework for statistical inference. As such, statistics is

in essence applied mathematics and should not be treated as a collection of recipe-like applications of computer-driven statistical techniques without any real understanding of their assumptions, limitations, proper implementation, and warranted interpretation of their results. This entry aims to summarize the basic results of frequentist inference in precise mathematical notation so as to avoid possible sources of confusion and misapprehensions that can result, according to critics, from texts that omit or water down such formulations.

Model-Based Frequentist Inference

Very few revolutions in scientific thought can be dated with any certainty, but *modern frequentist inference* is an exception. It was single-handedly founded by Ronald A. Fisher (1890–1962), who initiated a change of paradigms in statistics by recasting Karl Pearson’s descriptive statistics and curve fitting, into a model-based statistical induction that revolves around the concept of a prespecified parametric statistical model $M\theta(x)$. Before Fisher, the notion of a statistical model was implicit, and its role was primarily confined to the *description* of the distributional features of *the data in hand* $x_0 := (x_1, \dots, x_n)$, implicitly assumed to be independent and identically distributed (IID), using a frequency curve that belongs to the Pearson family. Unlike Pearson, who would commence with data x_0 seeking the best fitting frequency curve to approximate the histogram of x_0 , Fisher proposed to begin with (a) a prespecified statistical model (a hypothetical infinite population) and (b) view x_0 as a typical realization thereof: “Of what population is this a random sample?” (Fisher, 1922, p. 313), emphasizing that “the adequacy of our choice may be tested a posteriori” (Fisher, 1922, p. 314). A statistical model $M\theta(x)$, comprising the set of probabilistic assumptions imposed on one’s data x_0 , describes a stochastic mechanism that could have given rise to x_0 .

Prespecified parametric statistical model. Fisher’s concept of a prespecified statistical model can be formalized as a particular parameterization ($\theta \in \Theta$) of the observable stochastic process $\{X_k, k \in \mathbb{N} := (1, 2, \dots, n, \dots)\}$ underlying data x_0 , whose generic form is:

$$M\theta x = fx; \theta, \theta \in \Theta, x \in \mathbb{R}^{Xn}, \quad \text{for } \Theta \subset \mathbb{R}^m, m < n, \quad (1)$$

where $f(x; \theta)$ denotes the (joint) *distribution of the sample* $X := (X_1, \dots, X_n)$, $\mathbb{R}^{Xn}$ the sample space, and Θ the parameter space. $M\theta(x)$ plays a pivotal role in frequentist inference since it determines: (a) what constitutes a legitimate event on which $f(x; \theta)$ assigns probabilities, (b) appropriate data x_0 , and (c) legitimate hypotheses, and (d) optimal inference procedures; see Spanos (2019).

Specification. $M\theta(x)$ is selected to provide an idealized description of the stochastic mechanism that gave rise to data x_0 with a view to pose the substantive questions of interest framed in terms of θ . The choice of $M\theta(x)$ is based on selecting the appropriate probabilistic assumptions relating to $\{X_k, k \in \mathbb{N}\}$ to render x_0 a typical realization thereof, or equivalently $M\theta(x)$ accounts for all the chance regularity patterns exhibited by data x_0 ; this is established using misspecification testing. Chance regularities constitute recurring patterns in data x_0 that can be accounted for (modeled) using probabilistic assumptions from three broad categories: distribution, dependence, and heterogeneity; see Spanos (2019).

Example 1. The simple Normal model:

$$M\theta(x): X_t \sim \text{NIID}(\mu, \sigma^2), \theta := (\mu, \sigma^2) \in \mathbb{R} \times \mathbb{R}_+, t \in \mathbb{N}, \quad (2)$$

where $\mathbb{R} := (-\infty, \infty)$, $\mathbb{R}_+ := (0, \infty)$, and “ $\sim \text{NIID}(\mu, \sigma^2)$ ” stands for “distributed as Normal IID, with mean μ and variance σ^2 .”

Example 2. The simple Bernoulli model:

$$X_k \sim \text{BerIID}(\theta, \theta(1 - \theta)), x_k = 0, 1, \quad 0 \leq \theta < 1, k \in \mathbb{N}, \quad (3)$$

where “BerIID” denotes Bernoulli IID.

Example 3. The linear regression (LR) model:

$$Y_t = \beta_0 + \beta_1 x_t + u_t, u_t | X_t = x_t \sim \text{NIID}(0, \sigma^2), \theta := (\beta_0, \beta_1, \sigma^2) \in \mathbb{R}^2 \times \mathbb{R}_+, t \in \mathbb{N} \quad (4)$$

The **frequentist interpretation** of probability underlying statistical inference invokes the simple Bernoulli model in (3) and associates the probability of a binary event $A = \{X = 1\}$, $P(A)$, with the *limit* of relative frequencies $1_n = 1/n \sum_{i=1}^n X_i$ as $n \rightarrow \infty$, by appealing to the Strong Law of Large Numbers.

The *long-run metaphor* usually employed to conceptualize probability in terms of relative frequencies, does not *identify* probability with relative frequency; relative frequencies can only approximate (reflect) probabilities; see Spanos (2013).

Statistical inference. The *main objective* of model-based $[M\theta(x)]$ frequentist inference is to learn from data x_0 by *narrowing down* Θ as much as possible, ideally to a single point $\theta = \theta^*$, where θ^* denotes the *true* value of θ in Θ ; shorthand for saying that $M^*(x) = \{f(x; \theta^*)\}$, $x \in \mathcal{R}X_n$, could have generated data x_0 . In practice, $\theta = \theta^*$ is unlikely to be attained, except by happenstance, but that does not preclude learning from x_0 .

A key concept in frequentist inference that underlies both estimation and testing is the *likelihood function*:

$$L(\theta; x_0) = l(x_0) \cdot f(x_0; \theta), \theta \in \Theta, \quad (5)$$

where $l(x_0) > 0$ denotes a proportionality constant. Fisher defined the *maximum likelihood* (ML) estimator $\theta_{ML}(X)$ of θ to be the one that maximizes $L(\theta; x_0)$. He was also the first to draw a sharp distinction between the *estimator* $\theta(X)$ and the *estimate* $\theta(x_0)$ and emphasized the importance of using the sampling distribution of $\theta(X)$ to evaluate the effectiveness of the inference in terms of optimal properties. Neyman and Pearson (1933) introduced the idea of a likelihood ratio, $[L(x_0; \theta_1)/L(x_0; \theta_0)]$, for the null (θ_0) and alternative (θ_1) value of θ , as a basis for constructing optimal tests.

In principle, the *sampling distribution* $f(y_n; \theta)$, of a statistic (estimator, test, predictor), say $Y_n = g(X_1, X_2, \dots, X_n)$, is derived via:

$$F_n(Y_n \leq y) = \dots \{x: g(x) \leq y\} f(x; \theta) dx, \quad \forall y \in \mathcal{R}, \quad (6)$$

where $f(x; \theta)$ is given by the choice of $M\theta(x)$. In (6), the value of θ is always *prespecified*, taking two different forms relating to the underlying reasoning:

(i) *Factual* (point and interval estimation, prediction): evaluated under $\theta = \theta^*$, whatever value θ^* happens to be in Θ .

(ii) *Hypothetical* (testing): evaluated under various hypothetical scenarios based on θ taking different prespecified values relating to the null and alternative hypotheses, $H_0: \theta \in \Theta_0$ versus $H_1: \theta \in \Theta_1$, where Θ_0 and Θ_1 constitute a partition of Θ ; see Spanos (2019).

Estimation (point). The effectiveness of a point estimator $\theta(X)$ is evaluated in terms of how *accurately* pinpoints θ^* , using its optimal properties relating to its sampling distribution, $f(\theta(x); \theta)$, $x \in \mathcal{R}X_n$.

Example 1. For the simple Normal model in (2):

$$\begin{aligned} \text{(i)} \quad X_n &= 1n_k = 1nX_k \sim N_{\mu}, \sigma^2_n, \\ \text{(ii)} \quad s^2 &= 1(n-1)_k = 1n(X_k - X_n)^2 \sim \\ &\quad \sigma^2_n - 1\chi^2(n-1), \end{aligned} \quad (7)$$

where $N_{\cdot}$, and $\chi^2(\cdot)$ denote the Normal and chi-square distributions. These are *optimal* (effective in pinpointing θ^*) estimators of $\theta = \mu, \sigma^2$ since their sampling distributions in (7) indicate that they are both consistent, unbiased, sufficient, and X_n is also fully efficient; see Cox and Hinkley (1974). What is often not appreciated sufficiently is that the notation in (7) is misleading since the underlying reasoning is invariably omitted. For instance, (i) would be stated (under $\theta = \theta^*$) as:

$$X_n = 1n_i = 1nX_i \sim \theta = \theta^* N(\mu^*, \sigma^{*2}_n). \quad (8)$$

One might object to the unnecessary notation in (8), but then one needs why $E(X_n) = \mu$. The latter stems from the unbiasedness of X_n , which is defined by $E(X_n) = \mu^*$, involving factual reasoning.

Confidence interval (CI). A two-sided CI for θ takes the form of a random interval $L(X), U(X)$, where $L(X)$ is the lower bound and $U(X)$ the upper bound, aiming to overlay (cover) θ^* at some prespecified coverage probability $(1 - \alpha)$; one-sided CIs can also be defined by $L(X), \infty$ and $-\infty, U(X)$. The effectiveness of a CI is evaluated in terms of its expected length $E[U(X) - L(X)]$ for a prespecified coverage probability $(1 - \alpha)$. An optimum CI is the one with the minimum expected length for a given $1 - \alpha$; see Neyman (1937).

Example 1. For (2), the $1 - \alpha$ CI takes the form:

$$\begin{aligned} P(X_n - c\alpha^2(s_n) \leq \mu < X_n + c\alpha^2(s_n); \\ \theta = \theta^*) &= 1 - \alpha, \end{aligned} \quad (9)$$

where $s^2 = 1n - 1i = 1n(X_i - X_n)^2$, stemming from the distribution of the pivot:

$$\tau(X; \mu) = n(X_n - \mu)s \sim \theta = \theta^* St(n-1), \quad (10)$$

where “ St ” denotes the Student’s t distribution. Its expected length is:

$$\begin{aligned} E X_n + c\alpha^2 s_n - X_n + c\alpha^2 s_n = \\ 2c\alpha^2 \sigma_n \rightarrow 0 \text{ as } n \rightarrow \infty. \end{aligned}$$

Prediction is similar to estimation in terms of its underlying factual reasoning, but it differs from it in so far as it aims to find the best value of X_k beyond the observed data, say x_{n+1} .

Example 1. In light of (8), an optimal predictor of X_{n+1} is given by $X_{n+1} = X_n$, whose reliability is evaluated using the sampling distribution of the prediction error:

$$x_{n+1} - (X_{n+1} - X_n) \sim \theta = \theta^* N(0, \sigma^2(1 + 1/n)), \quad (11)$$

to construct a $1 - \alpha$ prediction interval:

$$PX_n - c\alpha 2s(1 + 1/n) \leq X_{n+1} \leq X_n + c\alpha 2s(1 + 1/n); \theta = \theta^* = 1 - \alpha. \quad (12)$$

Neyman–Pearson (N-P) testing poses questions on whether $\theta^* - \theta_0$, where θ_0 is the null value, is *statistically negligible* to data x_0 in terms of H_0 and H_1 by partitioning the parameter space Θ and operationalizing *statistically negligible* using error probabilities; see Neyman and Pearson (1933).

Example 1. For testing the following hypotheses in the context of (2):

$$H_0: \mu \leq \mu_0 \text{ vs } H_1: \mu > \mu_0, \quad (13)$$

an optimal Uniformly Most Powerful (UMP) test is defined by:

$$T\alpha := [\tau X = nX_n - \mu_0 s, C1\alpha = x: \tau x > c\alpha], \quad (14)$$

where $C1(\alpha)$ is the rejection region at significance level α . The N-P accept/reject H_0 rules relate to whether x_0 belongs to the acceptance $C0(\alpha) = \{x: \tau(x) \leq c\alpha\}$ or the rejection region.

The sampling distribution of $\tau(X)$ evaluated under H_0 (hypothetical) is:

$$\tau(X) = n(X_n - \mu_0)s \sim \mu = \mu_0 St(n-1), \quad (15)$$

is used to evaluate the Type I error probability and the p value:

$$P(\tau(X) > c\alpha; \mu = \mu_0) = \alpha, P(\tau(X) > \tau(x_0); \mu = \mu_0) = p(x_0). \quad (16)$$

The sampling distribution of $\tau(X)$ evaluated under H_1 (hypothetical) is:

$$\tau X = nX_n - \mu_0 \sigma \sim \mu = \mu_1 St\delta_1; n-1, \delta_1 = n\mu_1 - \mu_0 \sigma, \text{ for all } \mu_1 > \mu_0, \quad (17)$$

where δ_1 is the noncentrality parameter, is used to evaluate the power of $T\alpha$:

$$P(\mu_1) = P(\tau(X) > c\alpha; \mu = \mu_1), \text{ for all } \mu_1 > \mu_0, \quad (18)$$

which in conjunction with α defines its optimality; see Lehmann and Romano (2005).

The effectiveness of an N-P test $T\alpha$ is evaluated using the sampling distributions (15) and (17) of a test statistic $\tau(X)$, with its optimality calibrated in terms of a prespecified Type I error probability α , in conjunction with its power. For instance, the t test in (14) is UMP; see Lehmann and Romano (2005).

The test statistic $\tau(X)$ in (15) differs from the pivot $\tau(X; \mu)$ in (10) in two respects. First, μ is unknown in $\tau(X; \mu)$, but μ_0 in $\tau(X)$ is a known hypothetical value. Second, the underlying reasoning in (15) is hypothetical, under $\mu = \mu_0$, but in (10) is factual, under $\mu = \mu^*$. Having said that, the family resemblance between (15) and (10) provides the basis for the mathematical duality between optimal CIs and optimal N-P tests. For instance, using a pair of the test statistic and a pivot, a UMP test will give rise to a Uniformly Most Accurate (UMA) CI in the one-sided case, and a UMA Unbiased CI in the two-sided case as in (9).

N-P testing differs from Fisher's significance testing in two respects. The first is that adding an alternative hypothesis H_1 to the null H_0 brings into the testing the whole of Θ in conjunction with the error probabilities (Type I, II, power) that underlie the optimal theory of testing analogous to Fisher's optimal theory of estimation; see Fisher (1925). The second is that Fisher's p value is a post-data (x_0 is known) error probability that provides additional information beyond the accept/reject H_0 results.

Frequentist Error Probabilities

Regrettably, most statistics books use the vertical bar (|) instead of the semicolon (;) for the error probabilities in (16)–(18), misleadingly suggesting that they are *conditional* on H_0 or H_1 ; see Cohen (1994). Given that H_0 and H_1 are framed in terms of $\theta \in \Theta$, and θ is an unknown constant, the alleged conditioning is a misconception; see Spanos (2019). Another serious misconception is that error probabilities are often conflated with

the long-run relative frequencies associated with the metaphor underlying the frequentist interpretation of probability. For a sufficiently large number N of replications $x_1, x_2, \dots, x_N$, generated by the same $M\theta(x)$ as the original data x_0 , one can provide an empirical counterpart to the abstract error probabilities using the relative frequencies associated with the metaphor. It is crucial to emphasize, however, that error probabilities are genuine probabilities that calibrate the effectiveness of inference procedures, and the metaphoric long-run relative frequencies represent a way to envision such probabilities in more tangible terms; see Spanos (2013).

Inferential Claims for Estimation and Testing

What is often insufficiently appreciated in statistical inference are the inferential claims warranted by the different forms of inference as they relate to learning from data x_0 about θ^* . For instance, what claim does an optimal estimator $\theta(X)$ of θ can sanction about how the *estimate* $\theta(x_0)$ relates to θ^* ? Despite the widely held belief among textbook writers touting the use of effect sizes, the claim that $\theta(x_0)$ approximates close θ^* , denoted by $\theta(x_0) \simeq \theta^*$, is unwarranted, since $\theta(x_0)$ represents a single value over a wide range of possible values associated with $f(\theta(x); \theta)$, $x \in RX_n$.

A formal way to account for the uncertainty relating to $\theta(X)$ is to construct a CI for θ using $f(\theta(x); \theta)$, $x \in RX_n$, say:

$$P(L(X) \leq \theta < U(X); \theta = \theta^*) = 1 - \alpha, \quad (19)$$

as in (9). Unfortunately, the coverage probability $1 - \alpha$ in (19) relating to that uncertainty does not extend to the observed CI, $CI(x_0) = [L(x_0) \leq \theta < U(x_0)]$, since the latter either includes or excludes θ^* , post-data. Intuitively, one cannot assign a probability to $CI(x_0)$ since no random variable is involved. That is, the pre-data mathematical duality between CIs and N-P testing does not imply inferential duality, post-data. This renders unwarranted any (direct or indirect) probabilistic or likelihoodist assignment to values of θ within $CI(x_0)$; see Cumming (2012).

It is well known that the N-P testing accept (reject) H_0 does not warrant the claim that there is evidence for H_0 (H_1), and neither does a large

(small) p value. The main reason is that the process of going from an accept/reject H_0 result to post-data evidence for or against H_0 or H_1 warranted by data x_0 and test T_α needs to take into consideration the relevant statistical context:

$$(i) M\theta x, (ii) H_0: \theta \in \Theta_0 \text{ vs } H_1: \theta \in \Theta_1, \\ (iii) \text{ data } x_0 \quad (20)$$

Equation (20) includes the statistical adequacy of $M\theta(x)$, the framing of H_0 and H_1 , the test T_α as well as its power. This renders the commonly followed practice of detaching a testing result from (20) and reporting significance/nonsignificance using asterisks highly dubious. This is because all these results are vulnerable to the fallacies of acceptance and rejection; see Mayo and Spanos (2006).

Post-data severity. To account for (20) and address these fallacies, Mayo and Spanos (2006) propose an evidential interpretation of testing results based on post-data severity evaluation. In contrast to CIs, severity is based on post-data hypothetical reasoning, which provides a most potent tool for interrogating the data x_0 with a view to learn about θ^* since it includes an infinity of scenarios with the relevant error probabilities being equally ascertainable pre-data and post-data.

Reliable Inference and Trustworthy Evidence

What are the key steps to ensure reliable inference and trustworthy evidence?

Step 1. One begins with one or more questions of substantive interest and an appropriate data set x_0 given rise to by the stochastic phenomenon of interest.

Step 2. One studies several data plots to detect the chance regularities exhibited by x_0 (Spanos, 2019), and proceeds to (a) select an appropriate statistical model $M\theta(x)$ comprising probabilistic assumptions from three broad categories, distribution (e.g., N), dependence (e.g., I), and heterogeneity (e.g., ID), that could account for all the regularities in x_0 , as well as (b) adopt a parameterization $\theta \in \Theta$ in terms of which to frame the substantive questions of interest.

Step 3. Test the validity of the model assumptions (e.g., NIID) using misspecification testing. If any of these probabilistic assumptions are *invalid*,

then one should *respecify* $M\theta(x)$ (to account for the departures from the original assumptions) until a statistically adequate model is reached. This step is particularly crucial because Steps 4 through 6 presume the statistical adequacy of $M\theta(x)$, without which all inferences based on $f(\theta ML(x); \theta)$, $x \in RX_n$, are likely to be unreliable; estimators could be inconsistent, and the nominal error probabilities for CIs and optimal tests are likely to be very different from the actual ones; see Spanos (2019).

Step 4. One would proceed to derive the likelihood function, $L(\theta; x_0) \propto f(x_0; \theta)$, $\forall \theta \in \Theta$, which is then used to derive the ML estimator $\theta ML(X) = h(X)$ of each θ .

Step 5. Since $\theta ML(X) = h(X)$ is a function of X , its sampling distribution, $f(\theta ML(x); \theta)$, $x \in RX_n$, can be derived via (6), and that determines its optimal properties, such as unbiasedness, full efficiency, sufficiency, and consistency.

Step 6. Using $\theta ML(X)$, an *optimal* estimator of θ , one can proceed to draw inferences relating to learning from data about θ^* , by constructing CIs, testing hypotheses, and predicting, as described above.

In conclusion, reliable and effective inferences that would give rise to trustworthy evidence depend on two preconditions: (i) $M\theta(x)$ is statistically adequate (its probabilistic assumptions are valid for data x_0) and (ii) n is large enough for the inference procedure to have sufficient effectiveness to shed light on the substantive questions of interest.

STATISTICS

Our lives abound with data, from the grades of standardized tests to the indices on medical reports, from the number of friends on Facebook to the voting rates in presidential elections. A set of data is not very useful in itself; however, it needs to be analyzed and interpreted through data analysis, the process of examining what data mean and transforming data into useful information. This entry aims to introduce the science called *statistics*. Statistics, the science of collecting, organizing, describing, analyzing, and interpreting data, is an applied branch of mathematics associated with data-analytic procedures. Therefore, statistical data analysis is referred to as the process of examining what data mean, with the goal of using imperfect information—which is the collected data—to understand facts, make decisions, and make predictions about the world. It has applications to virtually every area in our lives. **This entry provides an overview of basic statistics as well as a foundation for understanding other**

entries on statistical inference in this encyclopedia.

Statistics used to be referred to as *any numerical indicator of a set of data* and was equated with “descriptive statistics” until Michael Cowles (1989) pointed out that statistics as a science is not only the practice of collecting and collating quantitative data but also the process of making inferences and drawing conclusions from them. Thus, making inferences is part of how numerical information is processed. Therefore, two elements constitute this section: *descriptive statistics*, which is about summarizing data using numbers or plots, and *inferential statistics*, which concerns using data to make conclusions or decisions. Whereas statistics is a science, a statistic is a number or value measured within some particular context. In order to carry out sensible and meaningful statistical procedures, it is important to understand (a) the context, (b) how and why these data were collected, (c) on which individuals or entities the data were collected, and (d) what questions to answer from the data.

Article I. Data and Data Sets

First, we need to know what data and data sets are; let us define some key terms. An *observational unit* is the person or thing on which measurements are taken, for which a number of different terms are commonly used. A *variable* is a measured characteristic of an observational unit. An *observed value or observation* is the actual value of a variable for every observational unit in a data set. Suppose we have a data set which are the SAT scores of 100 high school students. In this data set, the observational unit consists of the high school students, the variable is the SAT score, and the observed values are the 100 specific scores obtained by the students. In practice, data sets are often arranged in matrices, with rows for each observational unit and columns for variables.

Article II. Descriptive Statistics

Section 2.01 Measures of Central Tendency

One important way to describe statistics is by the measure of *central tendency*, also referred to as the *representative values*, which describe the center point of data distribution. Generally speaking,

data can be divided into two types: *categorical (or nominal) data* and *continuous (quantitative) data*. The distinction between these two types of data has implications for describing and making inferences from the data. Continuous data, also referred to as quantitative data, are data where the values can change continuously, and every little change in value provides information. Examples of continuous variables are height, weight, price, and rate. Continuous data can be rank ordered by value. In contrast, categorical data are used to make distinctions between different groups. Examples of categorical variables are type, gender, and ethnicity. Ranking categorical variables does not make conceptual sense, as no category is superior or inferior to another.

Data by itself can be noisy. For instance, Table 1 shows the prevalence of self-report obesity data among U.S. adults collected by the Center of Disease Control and Prevention (CDC, 2014). Here, listed are the obesity rate of 50 states plus the District of Columbia, but limited information can be obtained just from these data themselves. *Descriptive statistics* is used to construct simple descriptions about the characteristics of a set of quantitative data. An efficient way to describe the data is using *numerical indicators* or *summary statistics*, which are condensed data that best summarizes the data set. There are five important indicators to summarize data: minimum, first quartile, median, third quartile, and maximum. In this case, let us rearrange the data in increasing order, from the state of Colorado with the lowest obesity rate (20.5%), which is referred to as the *minimum (Min)*, to the state of Louisiana with the highest obesity rate (34.7%), which is referred to as the *maximum (Max)*. The state located at the midpoint between Colorado and Louisiana is Maryland, which ranks 26th among these 51 states and has a 27.60% obesity rate, the *median (Md or Mdn)*. Since median divides a distribution of quantitative data exactly in half, it is referred to as a positional or order measure. We can also summarize the data using the *first quartile*, a point with a quarter of values lower than it, and *third quartile*, a point with three quarters of values smaller than it. In this example, the first quartile is Connecticut, ranking the 13th (25.6), and the third quartile is Ohio, ranking the 39th (30.1%). Suppose the data collected are only for 49 states

Table 1 Prevalence of Self-Report Obesity among U.S. Adults (CDC, 2014)

<i>State</i>	<i>Prevalence</i>	<i>95% Confidence Interval</i>	<i>State</i>	<i>Prevalence</i>	<i>95% Confidence Interval</i>
Alabama	33.0	(31.5, 34.4)	Missouri	29.6	(28.0, 31.2)
Alaska	25.7	(23.9, 27.5)	Montana	24.3	(23.1, 25.5)
Arizona	26.0	(24.3, 27.8)	Nebraska	28.6	(27.7, 29.6)

plus DC (e.g., by removing Colorado from the data), the medium can be calculated by summing the two middle values (25th Maryland 27.60% and 26th Illinois 28.10%) and dividing them by two. Such logic of taking the proportional value can also be applied to the calculation of the first and third quartile.

Another way to describe continuous data is the *mean* (*sample mean*, M ; *population mean*, μ) which is also called the *arithmetic average*. The mean can be computed by adding all the scores in

a distribution of continuous data and dividing by the total number of scores. In the obesity rate example, in order to calculate the mean, the obesity rate of all 51 locations should be summed up first and the number is 1,425.20. Then, the mean can be obtained by dividing the sum obesity rate by 51, and the value is 27.95. On average, 27.95% of Americans reported themselves as obese. The mean is the most appropriate and effective measure of central tendency of a set of continuous data. However, it is sensitive to every change in

the data and nonresistant to extreme scores. For instance, if six students are supposed to take an exam but one was sick on that day, suppose the grades of those five students who took the exam are 90, 85, 100, 80, and 75, with an average of 86. But if all the six students are taken into account in calculating the mean, it will drop sharply to 71.7, which cannot reflect students' ability in a fair way.

Describing categorical variables is different from describing continuous variables, since rank order has little meaning for categorical variables. One way to describe categorical variables is by *frequency*, the number of occurrences. The score or value in a distribution that occurs most frequently is the *Mode* (*Mo*). The mode is appropriate to describe a set of nominal data, since categorical data are in the form of categories and no mathematical analyses (e.g., computing the mean) can be conducted in a meaningful way. In a nominal data set, the mode points out the category or numerical score that is most "typical" in terms of the number of times it appears. On the contrary, *antimode* is the score or value that appears the least frequently. Take the data set by the CDC as an example. Among the 10 states plus DC with least obesity rate, four are in Northeast, zero are in the Midwest, one are in the South, and five are in the West. So, the mode is the West while the antimode is the Midwest. Therefore, we can know from the data that states in the West are more likely to have a low obesity rate. In the cases that more than one category or score occur the same amount of times, such distribution is called *bimodal* if there are two modes or *multimodal* distribution if three or more modes are present in contrast to a *unimodal* distribution where only one mode exists. For instance, when we look at the 10 least obese locations, the distribution is unimodal, with only one mode, the West. However, the distribution can be bimodal if we only look at the first nine locations with least obesity rate, since both the West and the Midwest occur four times.

Median, mean, and mode are all measure of central tendency but differ in several ways. The mode is considered as the simplest measure of central tendency but is mainly used in describing categorical data. The median is appropriate for describing the center point of a set of quantitative data. One advantage the median has over the mode is that it takes into account the entire set of

scores in a distribution, rather than only one or a few scores. A more important advantage is that median is not swayed by extreme scores, referred to as *outliers*, and considered as a *resistant statistic*. On the flip side, however, the ability of the median to resist the influence exerted by extreme scores is also its primary weakness compared to the mean, as the median is not sensitive to changes in the data set. Therefore, the mean is considered as a *nonresistant statistic* in contrast to the resistant static of the median. There are some types of procedures that can be used to deal with extreme scores. For instance, *trimmed means* are obtained by removing the most extreme scores entirely, which is frequently used in calculating the grades evaluated by a panel of judges to avoid bias, and *Winsorizing* is to change the most extreme scores to the next less extreme scores.

Section 2.02 Measures of Dispersion

Providing central tendency summary statistics is not enough to understand data because measures of central tendency indicate little about how the scores in a distribution vary from this representative score. *Measures of dispersion* or *measures of variability*, usually applied to continuous data, report how much scores vary from each other or how far they are spread around the center point of a data set. Three common measures of dispersion are range, variance, and standard deviation.

Range (or *span*) is calculated by subtracting the minimum from the maximum in a distribution and indicates the distance between the highest and lowest scores in a distribution. Although the range provides a general sense of how much the data spread out across a distribution, a major problem is that it is a *nonresistant measure* and overly sensitive to extreme scores. In other words, one or two outlier can make a distribution look more dispersed than it actually is. To compensate for this problem, we can divide a distribution at the median to calculate the *lowsprad*, which is the range between the median and the minimum, and the *highsprad*, which is the range between the median and the maximum. Another way is to calculate the distance between the first and the third quartile, which yields that *interquartile range* (*IQR*), also referred to as the *quartile deviation* or *mid-spread*. The *IQR* can be further divided to

produce the semi-quartile range if finer gradations are needed.

Variance (sample variance, s^2 ; population variance, σ^2) is an index in squared units of the average distance of scores around the mean in a continuous data distribution. The variance can be calculated by summing the square distance of each value from the mean, and dividing the sum value by the number of values. The formula is $\sigma^2 = (X - \bar{X})^2/N$. The **deviation score** is the amount that one score differs from the mean. To sum up both the positive and negative deviation scores in a meaningful way, *sum of squares* (SS) is always adopted in statistics by adding the squared deviation scores cumulatively to (a) convert negative values into positive ones and (b) to amplify deviations. However, a variance score can be confusing because it is expressed in units of squared deviations about the mean rather than the original trait of measurement. Therefore, *standard deviation* (SD; *sample standard deviation*, s ; *population standard deviation*, σ) is more frequently used, which is a measure of dispersion that explains how much scores in a set of continuous data vary from the mean and is expressed in the original unit of measurement. Standard deviation is found by taking the square root of the variance. The mean and standard deviation are the measures of central tendency and dispersion reported most frequently by researchers when analyzing continuous data.

In statistics, the *standard score* (*standard normal deviates*) is often used to provide a common unit of measurement indicating how far any particular score is away from its mean. Researchers often report how many standard deviations a particular score is above or below the mean of its distribution. The most frequently type of standard score is the z -score, $z = (X - \bar{X})/SD$, which can be calculated by dividing its deviation score by the SD for the distribution. The data kept in their original unit of measurement and not converted to standard scores are *unstandardized* or *raw scores*. To interpret results in a more meaningful way, researchers usually convert raw scores into standard scores.

Article III. Probability and Statistical Inferences

Statistical inference is the process through which people can infer facts about a population using

noisy statistical data where uncertainty must be accounted for. During the inferential process, the sample mean, the standard deviation, and all the data level quantities are estimators. A statistical framework is needed to make those estimations described within the collected data set. In other words, an inference needs to be performed to generalize or use the data set collected to make conclusions beyond. Inferential statistics is mainly used to (a) estimate the characteristics of a population from data collected from a sample and (b) test for significant statistical differences between groups and significant statistical relationships between variables.

Because the size of most populations usually makes it too difficult or impossible to conduct a census, researchers have to study a *sample(s)* that are actually obtained from a targeted population and use the results from that sample to describe the population. Suppose that the Secretary of Education is interested in the GRE scores of all graduate students in the United States and has collected the scores of 100 graduate students. In this case, these 100 scores are the sample, and the scores of all graduate students in the United States is the population to be estimated. The population characteristics are *parameters* and the sample characteristics are *statistics*. The ultimate purpose for researchers is to generalize the results found from a sample back to its parent population. To achieve this, *parametric statistics* are often used as the estimation procedures. The statistics computed are called *estimates* and the formulas used to compute estimates are called *estimators*. Estimates of population parameters from sample statistics are possible when two assumptions are met: (a) the variable(s) of interest is distributed “normally” in the population being studied and (b) a random sample has been selected from that population.

Estimation procedures start with the assumption that scores on the variable(s) of interest in the population being studied are distributed in the shape of a symmetrical bell. This type of distribution is called a *normal distribution* or a *normal/bell-shaped curve*. For a normal distribution, the center point is in the exact middle of the distribution and is the highest point of the curve. The center point is the same as the mean, median, and mode of the distribution. Because of the

symmetrical shape of a normal distribution, researchers know the proportion of scores that falls within any particular area of the curve. In normal distributions, approximately 68% of the data values are within the range from the mean $\pm$ one *SD*. About 95% of data values are within the mean $\pm$ two *SDs*, and 99.7%, almost all of the data values are within three *SDs* of the mean (Figure 1). The curve continues to run on theoretically forever, a curve that runs on, getting ever closer to the line but never touching it is called *asymptotic*. The normal distribution provides information about the relative probability of a score failing in any given area of the curve. Understanding the normal distribution and the percentage of values falling in specific ranges has much implication to the inferential statistics.

Two characteristics are used to describe the distributions that may not be in the shape of a normal curve. First is the *kurtosis*, which refers to how pointed or flat is the shape of a distribution of scores. The shape of the normal curve, with the center point being the highest peak and the two tails leveling off in a similar way, is called *mesokurtic*. However, if a curve is tall and sharply pointed, with scores clustered around the middle, it is called *leptokurtic* or *peaked*. If a curve that is flat and more spread out because scores do not cluster around the middle but are dispersed rather evenly across the distribution, it is referred to as *platykurtic* or *flat* (Figure 2). The other characteristic is *skewness*, indicating that the majority of scores are toward one end of a distribution and the curve tails off across the rest of the distribution, providing an asymmetrical distribution. There are two types of skewness.

Figure 1 A Normal Distribution

Figure 2 General Terms of Kurtosis

Figure 3 Skewness

The first is *positively skewed* or *right-skewed distribution* which occurs when the tail runs to the right side of the curve. In this case, the mode is less than the median, which is less than the mean. The other type of skewness is the *negatively skewed* or *left-skewed* distribution which occurs when the tail runs to the left side of the curve. For a negatively skewed distribution, the mode is larger than the median which is larger than the mean (Figure 3).

Article IV. Random Sampling

The second assumption that informs estimation procedures is the selection of a random sample from the population being studied. The best assurance of a representative sample is random selection of population members, such that each population member has an equal chance of being selected for the sample. According to the *law of large numbers* (LLN), the average result will converge to the experiment's expected value if

an experiment is repeated for infinite times. A random sample is representative of a population because if a population is normally distributed on a variable, it is probable that a random sample drawn from that population will also be normally distributed on that variable. Another very important principle of inference that is related to sampling is the *central limit theorem* (CLT), which indicates that with any distribution of the original variable, for samples of a sufficiently large size, the real distribution of means is almost approximately normal at most of the times. The CLT addresses two aspects about sampling: (a) the larger samples give more accurate results than do smaller samples and (b) the random samples allow researchers to work under the normal curve. Therefore, random samples are highly concerned in statistical inference. It is always better to go with the random sample if we have a choice. However, if nonrandom samples are used, the normal distribution needs to be checked.

If we draw samples many times from the population, we will get a *sampling distribution*, which occurs when treating the random sample means as a distribution of data, and can also be formed of other estimators, such as percentages or median scores. The mean of sampling distribution means is referred to as the *grand mean*. During sampling, the observed value of an estimator varies from sample to sample. Such variability is called *sampling variability*, which is expected in statistics. Sampling variability occurs because of the randomness of the data. Because of the variability, *standard error of the mean* (SE_m) is applied to tell how much these random sample means are likely to differ from the grand mean of the sampling distribution. Standard error is calculated by dividing the standard deviation by the square root of the sample size, $SE_m = SD/N$.

Since we assume that any characteristic normally distributed in a population will also be normally distributed in a random sample selected from that population, it is possible to make estimation from the sample to the population. However, due to the sampling variability, the estimation is always a range, referred to as the *confidence interval* (CI), which is the range of scores of the random sample means (or other statistics). The

actual values of the upper and lower limits of a confidence interval are referred to as the *confidence limits*.

Confidence interval is highly associated with a *confidence level*, the percentage of random sample means (or other statistic) in a sampling distribution covered by the estimate of a population parameter. In other words, confidence level represents our confidence in estimating that an actual mean from a sample accurately represents the true population mean. Although the confidence level is always arbitrary, a typical cut-off used in social sciences is 95%, with a confidence interval being the mean $\pm 1.96 SE_m$. If we want a more precise range of mean $\pm 1.645 SE_m$, the confidence level drops to 90%, while if we want to be more careful and confident, we can choose 99% confidence level by including the mean $\pm 2.576 SE_m$. On the other hand, $(1 - \text{confidence level})$ is the probability of being wrong, referred to as *alpha* (α) or the *critical value*.

Article V. Statistical Testing

Statistical tests are also referred to as the *hypothesis tests*, or *tests of significance*, which is like a proof by contradiction in mathematics. Starting with an assumption, people will conduct statistical work under that assumption. Statistical tests generally consist of four steps: (a) determine the null hypothesis (H_0) and the alternative hypothesis (H_a); (b) collect the data and calculate a test statistic; (c) determine p value, or how unlikely the test statistics is if the H_0 is true; and (d) make a conclusion based on the p value and the context of the problem.

The first step is to formulate a hypothesis to test and specify an alternative to that hypothesis. Statistical testing is analogous to a court case, that a defendant is regarded as innocent until proven guilty. In statistics, the presumption of innocence corresponds to the *null hypothesis* (H_0). The H_0 often argues that nothing is happening, such as there is no relationship between the variables or there is no difference between the two groups. The H_0 is taken as a working hypothesis and is assumed to be true until it is disproved by the data. However, what the researchers really want to know is whether the opposite is true, by bringing up an *alternative hypothesis* (H_a or H_1), also called as the

research hypothesis. Just like the prosecutor who collects evidence to prove that the defendant is guilty, we conduct hypothesis testing to prove that H_0 is wrong and H_a is true, by seeing how likely it is that the H_0 happens by chance. If a direction of an outcome can be predicted, a *one-sided* H_a can be used, by stating that the outcome is either greater or less than 0. Otherwise, a *two-sided* H_a should be applied, by arguing that the outcome is not equal to 0. Suppose a public health researcher wants to evaluate the effect of a smoking intervention by conducting statistical testing. If the researcher knows that the intervention cannot make the tobacco use worse from theory or former research, they can use one-sided H_a . Otherwise, the researcher has to stick to the two sided H_a , if no clue of the intervention effect is available. In most situations, two-sided tests are appropriate.

So, the second step is to accumulate some evidence. Similar to the evidence collected by the police and prosecution in a court case, in statistics, we need to put together the evidence by analyzing our data. In order to make the data useful, we have to summarize the data into the *test statistic*, which is a numerical summary of the data. A test statistic is constructed assuming that H_0 is true. Then, we need to collect some data and summarize them into a test statistic.

Once the evidence has been collected and summarized for the judge and jury, the third step is to determine how unlikely the test statistic is if the H_0 is true with p value. p Value, a number between 0 and 1, transforms a test statistic into a probabilistic scale and quantifies how strong the evidence is against the null hypothesis. To decide whether the results could just happen due to chance, we wonder if H_0 is true, how likely it would be to observe a test statistic, or summary of our data of this magnitude just by chance. The numerical answer to this question is the p value. The smaller the p value, the more unlikely it is that we assume the H_0 is true, and the stronger the evidence we have against the H_0 . It is noteworthy that the p value is *not* a measurement of how likely it is that the H_0 is true. We can't put a probability value on H_0 , because it's not random. What a p value can tell is how likely the observed data would be, if an H_0 is true. It's a measure of the strength of the evidence against the H_0 .

So finally, we need to make a conclusion of whether the summary of our data of this magnitude is just by chance. In statistics, if the p value isn't small, we do not have strong enough evidence to support the H_a and have to conclude that our data are consistent with the H_0 . We can't conclude H_0 is exactly true, but we can't reject it either. Alternatively, if the p value is small, which means that we have data that are unusual enough, we have evidence to rule out the possibility that the H_0 is true, and we got the observed data by chance. In such case with a small p value, we conclude that we have sufficient evidence to reject the H_0 in favor of H_a .

STATISTICS, COMPLETENESS IN

Completeness is a probabilistic property that bestows a form of uniqueness on a statistic $h(X)$ in the context of a statistical model $M\theta(x)$ and crystallizes the link between sufficient and ancillary statistics.

Ronald A. Fisher's (1922) path-breaking paper recast Karl Pearson's descriptive statistics (Yule, 1916) into a model-based statistical induction grounded on the concept of a parametric statistical model whose generic form is:

$$M\theta(x) = \{f(x; \theta), \theta \in \Theta\}, x \in RX_n, \text{ for } \Theta \subset R_m, m < n, \quad (1)$$

where $R := (-\infty, \infty)$, $f(x; \theta)$ denotes the (joint) *distribution of the sample* $X := (X_1, \dots, X_n)$, RX_n the sample space, and Θ the parameter space. The likelihood function is defined by: $L(\theta; x_0) \propto f(x_0; \theta)$, $\theta \in \Theta$.

Example 1. The *simple Normal (N) model* is specified by:

$$\begin{aligned} X_t &\sim \text{NIID}(\mu, \sigma^2), \theta := (\mu, \sigma^2) \in \Theta := R \times R_+, \\ x_t &\in R, t \in N := (1, 2, \dots, n, \dots), \mu = E(X_t), \\ \sigma^2 &= \text{Var}(X_t), f_N(x; \theta) = (2\pi\sigma^2)^{-n} \exp - 1/2\sigma^2 \sum_{t=1}^n (x_t - \mu)^2. \end{aligned} \quad (2)$$

Example 2. The *simple Bernoulli (Ber) model* is specified by:

$$\begin{aligned} X_k &\sim \text{BerIID}(\theta, \theta(1 - \theta)), \theta \in \Theta := (0, 1), \\ x_k &= 0, 1, k \in N, \theta = E(X_t), \text{Var}(X_t) = \theta(1 - \theta), \\ f_B(x; \theta) &= \theta^n x^n (1 - \theta)^{n(1 - x)}. \end{aligned} \quad (3)$$

where $X = (1/n)k = 1/n X_k$.

Frequentist inference revolves around Borel measurable (well-behaved) mappings of the form:

$$h(\cdot) : RX_n \rightarrow R_k, n > k \geq 1,$$

Fisher (1922) named *statistics* $Y = h(X)$, such as estimators, confidence interval (CI) bounds, test statistics, and predictors, whose sampling distributions are derived via:

$$F(y) = P(Y \leq y) = \int \{x: h(x) \leq y\} f(x; \theta) dx, \quad \forall y \in R_k, \quad (4)$$

$f(y; \theta) = \partial F_n(y)/\partial y$, $\forall y \in R_k$, and provide the foundation of model-based frequentist inference. Of particular interest in this context are the sufficient and the ancillary statistics, introduced by Fisher in the early 1920s (see Lehmann & Scholz, 1992).

Sufficient. In the context of a statistical model $M\theta(x)$, a statistic $S := S(X)$ is said to be *sufficient* for θ if:

$$f(x | s; \theta) = f(x | s), \forall x \in RX_n, \quad (5)$$

or equivalently (see Cox & Hinkley, 1974, p. 22):

$$f(x; \theta) = f(x | s) \cdot f(s; \theta), \forall x \in RX_n, \forall s \in R_k. \quad (6)$$

That is, the distribution of the sample $f(x; \theta)$ can be separated into a product of:

- (i) a conditional distribution of X given $S = s$ that is free of θ and
- (ii) the marginal distribution of S which depends on θ .

The sufficient statistic S is said to induce the family of sampling distributions $\{f(s; \theta), \theta \in \Theta, s \in R_k\}$.

The statistic S is said to be *minimal sufficient* for θ , if for any other sufficient statistic $T := T(X)$ there exists a function $g(\cdot)$ such that $S = g(T(X))$; in practice S has the lowest dimension possible.

Ancillary. In the context of a statistical model $M\theta(x)$, a statistic $V := V(X)$ is said to be *ancillary* for θ , if its sampling distribution:

$$f(v), v \in R_{v,k}, n > k \geq 1,$$

is free of (does not depend on) θ (see Lehmann and Romano, 2005).

Intuitively, an ancillary statistic V contains *no information* about θ . The statistic V is said to be *maximal ancillary* for θ , if for any other ancillary statistic $U(X)$ there exists a function $g(\cdot)$ such that $U(X) = g(V(X))$; a maximal ancillary statistic V has the highest possible dimension k .

As argued by Erich Leo Lehmann and Fritz Scholz,

Ancillarity is in a certain sense the dual of sufficiency. If S is a sufficient statistic, then any inference can be based solely on S , and the conditional distribution of the full data set X given S is independent of its parameters. Conversely, if V is ancillary, inference may be based entirely on the conditional distribution of X given V , while the distribution of V is independent of the parameters. In this duality, a maximal ancillary corresponds to a minimal sufficient statistic. They differ however in that a minimal sufficient statistic is essentially unique and that explicit methods for its construction are available, neither of which is the case for maximal ancillaries. (1992, p. 33)

In an attempt to narrow down the class of possible maximal ancillary statistics, Lehmann and Scholz (1992) proposed restricting such statistics to those that are functions of the minimal sufficient statistics, that is, $V(X) = V(h(S))$.

Completeness, introduced by Lehmann and Henry Scheffé (1950), provides the key to elucidating the connection between sufficiency and ancillarity.

Completeness. The family of distributions defining a statistical model $M_\theta(x)$ is said to be *complete* if for any statistic $h(X)$ such that $E(h(X)) = 0$ for all $\theta \in \Theta$, that is, its mean is free of θ , implies that:

$$P_{h(X)=0} = 1, \text{ for all } \theta \in \Theta, \quad (7)$$

that is, $h(x) = 0$ with probability 1. If the Property (7) holds only for all bounded functions $h(\cdot)$, then the family is said to be *boundedly complete*. The intuition underlying (7) is that the only unbiased estimator of $0 \in \Theta$ is the zero function $h(X) = 0$. The same definition also applies to the sampling distribution $\{f(s; \theta), \theta \in \Theta, s \in R_k\}$ induced by a statistic $S := S(X)$.

For a sufficient statistics $S := S(X)$, completeness secures the uniqueness of certain properties based on a sufficient statistic S , such as unbiasedness and minimum variance.

Lehmann–Scheffé theorem. If there is a complete sufficient statistic $S := S(X)$ for θ in the context of a statistical model $M_\theta(x)$, then there is a unique unbiased estimator $\theta = h(S)$ of θ .

Intuitively, a complete sufficient statistic S contains no *ancillary* information in the sense that $g(S)$ is an ancillary statistic if and only if for some constant c , $P[g(S) = c] = 1$ for all $\theta \in \Theta$ (see Knight, 2000). This suggests that a way to construct ancillary statistics is to seek functions of the form $g(S)$ whose distribution is constant for all values of θ (free of θ), such as the residuals from the estimated model as argued next.

Sufficiency, Ancillarity, and Completeness

The amalgam of completeness, sufficiency, and ancillarity has given rise to several important results in statistical modeling and inference, including the following.

Lemma 1. If $S(X)$ is a *complete* sufficient statistics for θ , in the context of a statistical model $M_\theta(x)$, then it is a *minimal* sufficient statistic (see Lehmann & Scheffé, 1950).

Example 1 (continued). The simple Normal model in (2), in addition to having $S(X) = X_n = 1/n \sum_{i=1}^n X_i$, $s^2 = 1/n \sum_{i=1}^n (X_i - X_n)^2$ being a minimal sufficient statistic, $f(x; \theta)$ and $f(s; \theta)$ define families of distributions which are complete (see Lehmann & Romano, 2005).

Example 2 (continued). The simple Bernoulli model in (3), in addition to having $S(X) = X$ as a minimal sufficient statistic, $f(x; \theta)$ and $f(s; \theta)$ define families of distributions which are complete (see Lehmann & Romano, 2005).

Sufficiency principle (SP). If $S(X)$ is a sufficient statistic for θ , then any inference about θ should depend on the sample X only through $S(X)$. That is, exclusive reliance on $f(s; \theta)$ for inference purposes forfeits no relevant sample information since (6) implies that $f(x; \theta) \propto f(s; \theta)$, $\forall s \in R_k$.

A very interesting special case of the reduction in (12) arises when sufficiency and ancillarity arise together in the context of a complete family of distributions defining an ancillary statistic $V(X)$ and a complete minimal sufficient statistic $S(X)$ for θ .

Basu's theorem. For a statistical model $M_\theta(x)$, when $S(X)$ is a *complete sufficient* statistic, then it is *independent* of every *ancillary statistic* $V(X)$. Equivalently, $S(X)$ is independent of any statistic $V(X)$ whose distribution is free of (does not depend on) θ (see Basu, 1955).

This is a remarkable result which crystallizes the connection between sufficiency, ancillarity, and independence and has numerous applications in statistic (see Lehmann and Romano, 2005).

Basu's theorem has its most wide applicability in the context of the *exponential family* of distributions, introduced by Fisher (1934), which is complete and admits minimal sufficient statistics.

Exponential family. The *regular canonical form* of a p -parameter exponential family density is:

$$f(x; \theta) = a(\theta)h(x)\exp\theta^T s(x), \quad x \in R_X^m, \quad \theta \in \Theta \subset R_p, \quad (8)$$

$$a(\theta) = [1/c(\theta)], \quad c(\theta) = \int_{R_X^m} h(x)\exp\theta^T s(x)dx > 0, \quad \theta^T s(x) = \sum_{i=1}^p \theta_i s_i(x),$$

Θ is an open, convex subset of R_p , $p = \dim(S) = \dim(\theta)$, where “dim” denotes “dimension.”

The most important property of the family in (8) is that $S := S(X)$ is a minimal sufficient statistic whose sampling distribution also belongs to the same family:

$$f(s; \theta) = a(\theta)g(s)\exp\theta^T s, s \in R_p, \theta \in \Theta \subset R_{xp},$$

where $g(s) = \{s(x) = s\}h(x)$ when x is discrete and $g(s) = \{x: s(x) = s\}h(x)dx$ when x is continuous (see Brown, 1986).

An important property of the exponential family is that the joint distribution of $x_1, x_2, \dots, x_n$ also belongs to the exponential family:

$$f(x_1, x_2, \dots, x_n; \theta) = a(\theta)n\exp\theta^T i = 1n s(x_i)_i = 1n h(x_i), \forall x_i \in R_m, \theta \in \Theta \subset R_p.$$

The exponential family includes distributions such as Normal, inverse-Normal, Log-Normal, exponential, gamma, chi-square, beta, Dirichlet, Wishart, inverse Wishart, Rayleigh, Bernoulli (univariate, multivariate), Poisson, geometric, binomial (univariate and multivariate, with fixed number of trials), negative binomial (with fixed number of failures), and logarithmic. It excludes other known distributions, such as the Cauchy and the Student's t .

Complete Sufficiency and Similar Tests

Let the parameters of a statistical model $M\theta(x)$ be $\theta := (\phi, \psi) \in \Phi \times \Psi$, and $S := (S_1, S_2)$ is a sufficient statistic for $\theta := (\phi, \psi)$, where S_1 is sufficient for ϕ and S_2 is sufficient for ψ , that is,

$$f(s; \phi, \psi) = f(s_1|s_2; \phi) \cdot f(s_2; \psi), \quad \forall (\phi, \psi) \in \Phi \times \Psi. \quad (9)$$

For the hypotheses $H_0: \phi \in \Phi_0$ versus $H_1: \phi \in \Phi_1$, let a Neyman–Pearson (N-P) test be $T\alpha := \{d(X), C_1(\alpha)\}$, where $d(X)$ is a test statistic and $C_1(\alpha) = \{x: d(x) > c\alpha\}$ a rejection region. In general, the Type I error probability and the power of $T\alpha$ are functions of $\psi \in \Psi$ defined by:

$$\max_{\phi \in \Phi_0} P(d(X) > c\alpha; H_0) = \alpha(\psi), P(d(X) > c\alpha; H_1) = P(\phi, \psi), \forall \phi \in \Phi_1, \forall \psi \in \Psi,$$

specifying a *non-similar test* whose error probabilities are functions of ψ . However, when S is a *complete* sufficient statistic for $\theta := (\phi, \psi)$, one

can condition on $S_2 = s_2$ to render the Type I error probability and the power of $T\alpha$ free of ψ :

$$\max_{\phi \in \Phi_0} P(d(X) > c\alpha | S_2 = s_2; H_0) = \alpha, \\ P(d(X) > c\alpha | S_2 = s_2; H_1) = P(\phi), \forall \phi \in \Phi_1,$$

specifying a *similar test*. Statistical models with such complete sufficient statistics satisfying (9) are said to have a *Neyman structure* (see Lehmann & Romano, 2005).

Modeling Versus Inference: A Case for Ancillarity

Another important result that follows from a combination of a complete sufficient statistic $S(X)$ and a maximal ancillary statistic $V(X)$ for $\theta \in \Theta \subset R_p$ in the context of a statistical model $M\theta(x)$.

Consider a one-to-one mapping from the sample X into two vector statistics $S(X)$ and $V(X)$:

$$X \rightarrow (S(X), V(X)), X (n \times 1), S(X) (p \times 1), \\ V(X) ((n - p) \times 1), \quad (10)$$

$$\dim X = \dim V + \dim S, \\ J = \det \partial s \partial x : \partial v \partial x > 0 \quad (11)$$

In the general case where *no restrictions* are imposed on (S, V) , $f(x; \theta)$ can be separated into:

$$f(x; \theta) = J \cdot f(s, v; \theta) = J \cdot f(s|v; \theta) \cdot f(v; \theta) = J \cdot f(v|s; \theta) \cdot f(s; \theta), \forall s, v \in R_{sp} \times R_{vn-p}. \quad (12)$$

What is intriguing about (12) is how it simplifies when one assumes that:

(a) $S := S(X) = (S_1, \dots, S_p)$ is a *complete (minimal) sufficient* statistic,

(b) $V := V(X) = (V_{p+1}, \dots, V_n)$ a *maximal ancillary* statistic. Basu's theorem implies that:

$$f(x; \theta) = J \cdot f(s; \theta) \cdot f(v), \forall s, v \in R_{sm} \times R_{vn-m}, \quad (13)$$

and (c) $S(X)$ and $V(X)$ are *independent*.

The clear separation of $f(s; \theta)$ and $f(v)$ in (13) stemming from (c) implies that inference can be based exclusively on $f(s; \theta)$ (SP) since the likelihood function reduces to $L(\theta; x_0) = c(x_0) \cdot f(s; \theta)$, $\forall \theta \in \Theta$, where $f(v)$ becomes a component of the proportionality constant $c(x_0)$. On the other hand, since $f(v)$ is free of θ , it can be used to validate $M\theta(x)$ using misspecification testing since the error probabilities in testing its validity do not depend on θ (see Spanos, 2019).

The p-parameter exponential family of distributions is tailor-made for this since it provides a general framework where one can separate the inference from the modeling facets.

Example 1 (continued). For model evaluation purposes the simple Normal model in (2), we know that $S = (X_n, s_2)$ is a minimal sufficient statistic for $\theta = (\mu, \sigma^2)$. Not surprisingly, the maximal ancillary statistics relates to the *residuals*:

$$u_t = (X_t - X_n) \sim N(0, (n-1)\sigma^2), t \in N,$$

whose distribution depends on σ^2 . However, we know that:

(i) the residuals $u_1, u_2, \dots, u_n$ are independent of X_n , (ii) X_n and s_2 are independent, and thus Basu's theorem implies that (iii) the *studentized* residuals $v := v_1, v_2, \dots, v_n$:

$$v_t = (X_t - X_n) / s_2 \sim St(n-1), t = 1, 2, \dots, n,$$

are independent of X and s_2 . Hence, v constitutes an ancillary statistic since its distribution is free of (μ, σ^2) , which is also a function of the minimal sufficient statistic X, s_2 (see Lehmann and Romano, 2005). This renders the studentized residual statistic v ideal for model validation purposes. Given that the distribution of $v_1, v_2, \dots, v_n$ are singular, $S := (X, s_n)$ and $V := (v_3, \dots, v_n)$ constitute the relevant minimal sufficient and maximal ancillary statistics, respectively; $\text{rank}(X) = n$, $\text{rank}(S) = 2$, and $\text{rank}(V) = n - 2$. As argued by Spanos (2019, chap. 15), the residuals $\{(v_t, v_{t+2}), t = 3, 4, \dots, n\}$ can be used to construct joint misspecifications tests based on auxiliary regressions to ascertain the validity of the model $[M\theta(x)]$ assumptions, for many statistical models.

STRUCTURALISM (INTRODUCTION TO THEORY)

History is replete with views and movements sharing the same name, though exhibiting considerable divergence in detail. The term *structuralism* is no exception. Structuralisms have emerged in fields as diverse as anthropology, architecture, economics, linguistics, literary criticism, mathematics, philosophy, psychology, and sociology. What they all have in common is an emphasis on structural analysis—that is, on understanding a given system by paying close (and sometimes exclusive) attention to the relations that organize its elements. Even within philosophy, structuralist views have popped up in a number of subfields including aesthetics, the philosophy of language, the philosophy of mathematics, and the philosophy of science. This entry focuses on two prominent and interrelated structuralisms in the

philosophy of science, namely structuralism in the scientific realism debate and structuralism in the scientific theory and representation debates.

Structuralism in the Scientific Realism Debate

The scientific realism debate is primarily a discussion over what epistemological (sometimes also over what metaphysical and axiological) commitments one should endorse vis-à-vis scientific theories and models. Roughly speaking, scientific realists—henceforth just *realists*—hold a generally positive epistemic attitude toward theories and models. In more detail, they claim that our best—our most explanatorily and empirically successful—theories and models are likely to be approximately true or to at least contain some nonnegligible truth content in relation to both observable and unobservable features of the world. By contrast (and equally roughly), scientific anti-realists—henceforth just *anti-realists*—hold a generally negative epistemic attitude toward theories and models. That is, they claim that theories and models, even the best ones, are unlikely to contain nonnegligible truth content (and hence are unlikely to be approximately true) in relation to both observable and unobservable features of the world or that we are never in an epistemically secure enough position to assert that they do.

It is worth dwelling a bit on the distinction between observable and unobservable features of the world. Crudely put, observable features are those that are directly detectable through our unaided sensory organs. Unobservable ones are those that resist such detection. Thus, animals, volcanoes, and dwarf planets are observable but viruses, atoms, and subatomic particles are not. In effect, anti-realists are skeptics about many of the posits of modern science because drawing ontological conclusions from instruments typically involves long chains of inferences, each of whose links can be questioned. For example, the detection of subatomic particles relies on circuitous inferences that begin with the observable tracks they presumably leave behind in particle accelerator chambers. The significance of the observable–unobservable distinction has been questioned by some realists. Generally speaking, the realists are

happy to concede the distinction but argue that instruments nonetheless provide some epistemic access to some posits.

Structuralism in the scientific realism debate is a view that has developed against the backdrop of several renditions of the debate. It is more commonly known as *structural realism*, although, as we shall soon see, not all views under its banner are realist. Structural realists argue that our best scientific theories and models have no trouble providing accurate descriptions of various features of the observable world but are limited in their ability to accurately describe the unobservable world. More formally, such theories and models describe the unobservable world up to isomorphism (a technical notion which means, roughly, having the same form or structure). On this view, we can only hope to describe the structure of the unobservable world. One of the earliest motivations for the view appears in the work of Henri Poincaré (1854–1912) and is historical in nature. Crudely put, we can only know the structure of the unobservable world because when we examine the history of science, we discover that any description seeking to go beyond structure comes undone at the next scientific revolution. Structure, contrariwise, seems to survive in at least some approximate form. To give some examples, although the ontological posits in classical descriptions of thermal, optical, electrical, and magnetic phenomena have been supplanted by distinct ontological posits in nonclassical ones, parts of the structure of those descriptions have remained invariant. Let's take the case of optical phenomena. We no longer believe in light as a vibration in an all-pervading elastic medium—what was once known as the *luminiferous ether*. Even so, we use some of the same mathematical structures, such as Henri Fresnel's equations, to predict and explain the corresponding phenomena. To sum up, despite having to discard ontological posits such as the ether, some of the same mathematical structures remain with us. This gives some *prima facie* reason to believe in structural realism. More broadly, if the history of science does indeed follow this pattern, we have good grounds for endorsing structural realism over any other form of realism or anti-realism. (Other cases of structural

continuity have also been proposed—see, e.g., Votsis & Schurz, 2012.)

There are more than a few structural realist views out there. As we cannot explore all of them here, we will restrict our attention to the general divide between the epistemic and ontic families. What we have said so far chimes well with both families. The main difference between them is that the ontic structural realists employ revisionary ontological considerations to reach the same epistemic conclusions (see French, 2014, for details). To be more precise, they argue that the reason why we cannot know anything beyond the structure of the unobservable world is effectively because only structure matters. This claim has been interpreted in distinct ways. In the extreme, it is taken to mean that only structure exists. Objects are just placeholders for the intersections of relations and thus do not strictly speaking exist but are at best useful fictions. A more moderate reading allows for the existence of objects but denies that such entities are individuals and hence demotes their overall role in understanding the unobservable world. Motivations for ontic structural realist views vary, but they are typically drawn from quantum physical considerations. Those who advocate the moderate reading, for example, point out that fundamental objects in quantum physics lack individuality because they fail Leibniz's principle of the identity of indiscernibles, which holds that two objects sharing all their properties are in fact identical.

As alluded to earlier, not all structuralists in the scientific realism debate are realists. There are also structural anti-realists, though they often go by more affirming names like *structural empiricists* or *empiricist structuralists*. The essence of such views is that even though we must remain agnostic with respect to the exact nature or denizens of the unobservable world, our best theories still give us a pretty good description of the observable world. In particular, the claim is made that, if we understand theories as collections of structures, then theories can be used to adequately represent only structures in the observable world. Of note here is that this conception of theories as collections of structures is shared by some of the structural realists, such as Steven French. It is also a

good segue into other types of structuralism, which we will explore in the ensuing section.

Objections to structuralist views abound (for an in-depth discussion of arguments for and against structural realism, see Frigg & Votsis, 2011). Some are more serious than others. Structural realism has been accused of being either too weak to be realist (and hence collapsing into empiricism) or too undistinctive (and hence collapsing into traditional versions of realism). The latter accusation affects also structural anti-realists, their view presumably collapsing into traditional versions of anti-realism. Ontic structural realists have been accused of being incoherent—this is predominantly an objection to the extreme version of the view outlined earlier, since it seems to assert that there can be relations without relata. More generally, all structuralist views in the scientific realism debate seem to be affected by the following questions: (1) What formal frameworks need to be in place to do justice to the requisite notion of structure? and (2) What ontological category plays the role of the non-structural features of the world? As to the first question, the proposals range from second-order logic (and particularly the device known as the *Ramsey sentence*) to set theory, quasi-set theory, and category theory. As to the second question, the proposals range from qualities to intrinsic properties, monadic properties, and haecceities. It is worth noting that this objection runs deeper than the others and has been justifiably underscored by critics.

Structuralism in the Scientific Theory and Representation Debates

The scientific representation debate is primarily concerned with the question of how scientific theories represent their target systems. Taking a stance in this debate often means taking a stance in the debate over the nature of scientific theories. The two main stances in the latter debate are the syntactic view and the semantic view. (A third view, known as the *pragmatic view*, seems to be emerging in popularity, though it is not currently systematic enough or sufficiently distinct from pragmatic-oriented versions of the other two views to deserve attention here.) The *syntactic view* is taken to construe theories as sets of

sentences axiomatized in some meta-mathematical framework, for instance, first-order predicate logic with set theory. By contrast, the *semantic view* is taken to construe theories as sets of models, where a model is a set-theoretic structure. Thus, depending on which view of theories one advocates, the representation relation seems to manifest itself in distinct ways: Target systems are represented by linguistic entities—that is, by sentences—if one follows the syntactic view, or by extralinguistic entities (in other words, abstract set-theoretical structures) if one follows the semantic view.

It is tempting to assume that the semantic view alone deserves the appellation *structuralism* in the scientific theory and representation debates and, additionally, that it alone aligns with structuralism in the scientific realism debate. After all, the semantic view typically construes the representation relation as a mathematical morphism, for example an isomorphism, between theories and the world. Moreover, it explicitly conceives of theories in terms of set-theoretic structures, and such structures, as we have seen, offer one of the ways through which structuralists in the scientific realism debate express the commitments of their views. Such an assumption seems ill-advised. One reason to resist it stems from the fact that some versions of structural realism, namely Ramsey-style structural realism (see Worrall, 1989), are married to the syntactic view of theories. Named after its inventor, the philosopher-mathematician Frank Ramsey, Ramseyfication is achieved by first expressing theories in predicate logic and then logically weakening them by stripping away the interpretations of all non-logical terms meant to denote unobservables. (It is worth noting that the process leaves intact the interpretations of non-logical terms intended to denote the observables. Ramseyfied theories thus restrict what features of the unobservable world can be adequately represented to their logical structure.

Another reason why we should not be tempted by the foregoing assumption stems from the fact that the two views have been variably interpreted. Once we put aside naive readings of each view, the differences between them appear to be few and superficial, if not altogether absent. For example, the syntactic view need not take the

sentences which make up theories to be uninterpreted. Indeed, for each such set of sentences, there is in fact a corresponding set of models which makes those sentences true. Conversely, the semantic view need not take the models which make up theories to be detached from sentences. After all, the function of models, construed as set-theoretical structures, is to make sentences true. (In fact, that's what we mean when we say that models satisfy a theory. The notion of *satisfaction* is central to any discussion of models in the model-theoretic sense.) Other objections that seek to drive a wedge between the two views can be, and have been, questioned on the basis of different interpretations. These include the reputed requirements (attributed to the syntactic view) that theories should be axiomatized and the metamathematical framework should be first-order predicate logic—see Lutz (2012) for a counter—and the reputed requirement (attributed to the syntactic view) that only mathematical (vs. metamathematical) frameworks must be used in analyzing theories and in representing target systems. To summarize, when offered more sophisticated construals, the semantic and the syntactic views seem equally qualified to earn the appellation *structuralist* in their conception of theories and of the representation relation. Both also appear to be a good fit with structuralism in the scientific realism debate.

Thus far, we have presupposed that the representation relation is a kind of mapping between the structures of theories and the structures of the world. There are, however, other accounts of representation which may not be as amiable to the structuralist ideology. Indeed, such accounts purposely try to dissociate themselves from that ideology. On the similarity account, a theory or model represents a target system just in case it is similar to that target system in some relevant respects. Which respects are relevant is sometimes deliberately left unspecified to deal with the kinds of cases that the structuralists are accused of being incapable of handling, namely cases where no direct mapping can be established between theories and the world. The trouble with this approach is that, unless its advocates provide some sort of principled way to circumscribe the similarity

relation, they risk trivializing the view. After all, and as countless philosophers have pointed out, everything is similar to everything in some respect or other. A more promising approach to the similarity account is to insist that the relevant respects are context dependent. Another notable account of the representation relation is *inferentialism*. On this account, a necessary condition for a *surrogate* (the entity that does the representing) to represent a target system is that we can draw inferences from the former to the latter. Inferentialism prides itself in being neutral with respect to the kinds of entities that can be used as surrogates. They can be theories; models; physical, abstract, or fictional objects; and so on. Just like in the case of the similarity account, this strength of the inferentialist account also proves to be a potential weakness. It is always possible to draw some inferences from one object or system to another. Unless the permissible inferences are restricted, the inferentialists risk trivializing their view.

The success or failure of the similarity and inferentialist accounts depends on what kind of information is vital for a representation to genuinely tell us something about target systems. If the requisite kind of information must always be structural in nature, then the two views are faced with an unpalatable dilemma. Either construe the representation relation in a nonstructural way and therefore end up missing the mark or construe it in a structural way and end up collapsing into structuralism.

Conclusion

Whether it is a view within the scientific realism, the scientific theory or the scientific representation debates, structuralism has proved to be highly influential and resilient. Those who wish to study the epistemological, metaphysical, and methodological aspects of these debates are unlikely to make any headway unless they pay such views the attention they deserve.

SYNTAX (INTRODUCTION TO THEORY)

Syntax is the set of rules and principles that govern the structures of sentences; the word also refers to the study of these rules and principles and is thus one of the branches of linguistic knowledge, alongside phonetics, phonology, morphology, semantics, and discourse. Sentences are the basic unit of syntactic analysis; they can be simple, compound, or complex according to their structural composition. The complexity of predication and coherence between the constituents defines the complexity of a sentence. Accordingly, sentences may range from one-word syntactic units to paragraph-long complex structures. Traditionally, the main feature of a sentence has been the expression of one complete thought through logically organized and coherently connected words. As a discipline, however, modern syntax conceives the sentence as a unit consisting of subject and predicate, since a thought can be expressed by a single word, which may not be a sentence.

The term *syntax* derives from the Greek word *syntaxis* meaning *arrangement*. The words are arranged in an organized and structured manner to produce a single logical statement, thought, exclamation, or question. The arrangement of words reveals the relationships of meanings within one syntactic structure. The relationship is coherent, with cohesively bound concepts, meanings or lexico-phraseological units. Syntactic studies focus on sentence structure and connections within and between sentences. Building a syntactic tree is the main basis of syntactic analysis. It displays relations and hierarchies between sentence constituents most vividly.

Therefore, the sentence is the largest unit to which the syntactic rules apply. It is an independent linguistic unit. However, sometimes a sentence omits a part of its structure, for instance, when producing elliptical sentences. In this case, the sentence becomes dependent on the previous or following sentences. Moreover, the production of a complete paragraph requires the logical, cohesive, and coherent connection between sentences that form a completed sequence of thoughts, ideas, and statements expressed in one paragraph.

Approaches to Syntactic Analysis

The fundamental feature of any given natural language is to distinguish logically constructed sentences from illogical sequences of words that are not sentences. Thus, linguistic analysis is concerned with identifying *grammatical* and *ungrammatical* sequences of phonemes, lexical, or grammatical units. By grammatical sequences, it is implied that phonemic, morphemic, or lexical units are arranged according to the rules that are accepted in a given language as norms in order to produce sentences that make sense and are understandable to all the speakers of the language. In his classic 1957 work *Syntactic Structures*, Noam Chomsky puts forward the major principles of syntactic analysis and hence sets the foundations of generative grammar, which imply the generation of innumerable number of sentences by finite number of grammatical rules.

One of the first things to do in analyzing a sentence is to identify groupings within it, the process often referred to as *sentence parsing*. The groupings may range from morphemes to groups of words that

are often called *sense groups*. The groups are called *verb phrase*, *noun phrase*, *adjective phrase*, and so forth. Phrases can in turn be divided into their constituent words. The words can be further subdivided in their constituent morphemes. Therefore, a sentence can be viewed as a hierarchical structure that can be analyzed according to its constituent parts. Furthermore, simple sentences can be joined into more complex structures by different linking devices, such as conjunctions, which are divided into coordinating and subordinating types. For example:

- Tom went to work and met his colleagues (here, *and* acts as a coordinating conjunction).
- Tom went to work, because he had to meet his colleagues (here, *because* acts as a subordinating conjunction).

In modern linguistics, many linguists emphasize the concept of *fuzziness* in syntactic structures. *Fuzziness* implies the production of syntactic structures that are not quite grammatical but are not totally ungrammatical either, meaning that individual speakers produce syntactic structures that do not strictly follow grammatical rules but neither are they incorrect.

Sentence Analysis Through Immediate Constituents and Parsing

One of the most widely used techniques of syntactic analysis is the division or splitting of a sentence into its immediate constituents. The process is usually represented through the construction of a diagram that vividly displays the hierarchical composition of the parts of a sentence and their interrelation with each other. However, the problem with immediate constituent analysis is the fact that the diagram does not inform us about the identity of the sentence elements that they disclose, nor does it reveal the interrelation between the sentences (i.e., active-passive, statement-question). In order to address the issue and make the analysis more informative, it has been suggested to label the parts of a sentence that are disclosed, that is, to indicate the subject, object, and predicate of a sentence.

Another way to approach the analysis is the aforementioned method of *parsing*, or identifying

sense groups within the sentence, such as noun phrase (NP), verb phrase (VP), and so forth, thus making the analysis more informative and thorough.

Cohesion and Coherence

The most important binding devices that hold the syntactic structures are cohesion and coherence. Coherence is achieved through syntactical features such as the use of *deictic*, *anaphoric*, and *cataphoric* elements or a logical tense structure, as well as presuppositions and implications connected to general world knowledge.

Regarding cohesion, M. A. K. Halliday and Ruqaiya Hasan identify the following categories of cohesive devices that create coherence in a text: reference, ellipsis, substitution, cohesion, and conjunction. *Anaphoric* and *cataphoric references* are the significant constituents of building coherent and cohesive connections between and within sentences. *Anaphoric* reference takes place when the reference is made to someone or something that has already been mentioned previously. *Cataphoric* reference is the opposite of anaphoric reference; that is, it refers to someone or something that will be mentioned after the sentence under discussion. More specifically, something is introduced before it is identified. Referents can help us disambiguate a sentence with an indefinite and another operator by anaphoric linkage. Referential anchoring means that the referent of the specific NP is functionally dependent on the referent of another expression. Thus, specificity and familiarity conditions are created that act as binding tools in building the cohesive texts and structures.

Elliptical sentences leave out their constituent parts because the surrounding structures make it possible to make sense of the meaning that is expressed or implied by the sentence.

In the case of *substitution*, a word is not omitted, as in ellipsis, but is substituted for another, more general, word. For example, *which book would you like? I would like the one on the top shelf*, where *one* is used instead of repeating *book*. The same holds for pronouns, which replace the noun. For example, *book* is a noun, and its pronoun could be *it*, as in, *I bought the book because it was interesting*.

Regarding *cohesion*: In linguistics, *grammar* refers to the logical and structural rules that govern the composition of clauses, phrases, and words in any given natural language. The term refers also to the study of such rules, and this field includes morphology and syntax, often complemented by phonetics, phonology, semantics, and pragmatics.

As previously mentioned, *conjunctions* express coordinating and subordinating connections between the parts of complex sentences. A conjunction establishes a relationship between two clauses. The most basic but least cohesive is the conjunction *and*, which mainly expresses coordinating connections. Furthermore, *transition* words are conjunctions that add cohesion to text and include *then*, *however*, *in fact*, and *consequently*. Conjunctions can also be implicit and deduced from correctly interpreting the text.

Subordination and Coordination

Coordination and subordination are ways of making sentences more complex. In coordination, the clauses that are linked are of equal grammatical status, whereas in the case of subordination, also known as *embedding*, one clause functions as part of another—that is, part of the main clause—and is dependent on it. The following examples serve to illustrate the point: *John went to Paris and Nick went to Rome* (the case of *coordination*, i.e., both clauses have equal status); *John went to Paris, because he did not want to go with Nick to Rome* (the case of *subordination*, in which the second clause is subordinate to the main clause).

SYNTAX (SCIENTIFIC AND EMPIRICAL)

Language is a uniquely human capacity. Within this capacity, organizing words into logically coherent and comprehensible structures—sentences—is the most complex human faculty. These sentences, or syntactic structures, present the core of syntactic analysis, more precisely, of syntax. The major concern of syntax is the study of syntactic structures in all their varieties and complexities. Syntax may lie within empirical and scientific frameworks.

Empirical Framework of Syntax

The empirical framework of syntax is concerned with the practically observable processes of arranging words into sentences, identifying parts of sentences, and parsing sentences into sense groups and other readily analyzable parts. One of the major realms of empirical syntax is syntactic typology.

Syntactic Typology

The order of subjects, verbs, and objects in sentences determines the typological classification of languages according to syntactic structures. Apart from variation in the basic order between subjects, verbs, and objects, languages can also reveal other types of variation. As an instance, some languages show more word-order possibilities than others. This may be attributed to morphological properties; that is, how much case morphology exists in noun phrases in the language. Generally speaking, languages with well-developed case morphology have a freer word order than languages with fewer case categories (e.g., Caucasian/Kartvelian/languages with free word order, as opposed to Indo-European languages with fixed word order in a sentence).

Intuitively, it is easy to understand the reasons behind this fact. Case morphology readily indicates the function of a noun phrase, whereas in the absence of case morphology, the language has to look for alternative ways of indicating which constituent has subject function, which is the direct object, and which constituent is the indirect object. Implementing a strict word order carries out this duty of identifying the functions of the constituent parts of a sentence.

Hence, we can classify the languages according to syntactic typology; in other words, through identifying the types of syntactic structures that are characteristic of a certain language we can attribute it to a specific class of languages that have similar syntactic structures. Taking a step further, syntactic typology allows for identifying universals across languages that in its turn facilitates cross-language comparative analysis.

Clause Grammar and Structure

Another significant field of empirical syntax is that of clause grammar and structure. It is well known that almost all languages contain complex syntactic structures alongside simple sentences that possess straightforward and basic syntactic structures. Therefore, syntax often concerns itself with clause grammar rather than sentence grammar. This is primarily because complex sentences are made up of clauses that are easily subject to syntactic analysis. A clause is a unit structured

around a verb phrase. Together with the verb phrase, there are clause elements, which are realized by phrases or by embedded clauses. The core of the clause can be divided into two main parts: the *subject* and what is traditionally called the *predicate*. These usually correspond to a nominal part and a part with a verbal nucleus that semantically is equivalent to a *topic* and a *comment*. Together, these parts express a proposition. The predicate in its turn can be broken down into a verb phrase and several complements (objects, predicatives, adverbials). Thus, the main constituent elements of a clause are subject, verb phrase, subject predicative, direct object, indirect object, prepositional object, object predicative, and adverbial. Each element plays a role in the syntactic analysis of a clause and in deriving its meaning and its relations to surrounding structures.

Subordinate clauses may have various syntactic functions, such as nominal clauses, exclamative clauses, relative clauses, adverbial clauses, and so forth. Identification of the structural and functional features of clauses and the analysis of complex sentences facilitate the formulation of principles that help us trace the development and evolution of languages.

Syntactic Gradience and Fuzzy Syntactic Structures

In modern empirical linguistics, a growing number of linguists emphasize the concept of *fuzziness* in syntactic structures. *Fuzziness* implies the production of syntactic structures that are not quite grammatical but are not totally ungrammatical either; individual speakers produce syntactic structures that do not strictly follow the rules of grammar but neither are they incorrect. Hence, we get the condition of *syntactic gradience*, whereby the boundaries between grammatical and nongrammatical structures have become blurred. Therefore, more scientists hold the positivist stance toward syntactic analysis of structures by merely *describing* the syntactic idiosyncrasies of languages and producing the findings on usage frequencies and conditions of certain constructs rather than standardizing the norms. The shifty nature of languages offers more possibilities for positivist studies rather than normative standardization of grammatical forms,

be they on the level of phonology, morphology, syntax, or semantics.

Conditional Syntactic Structures

Conditional sentences offer several interesting insights into empirical syntax, namely, the syntactic construction of special types of sentences. *If*-clauses standardly have the form of declarative sentences and are introduced into the scope of *if* without changes. However, sometimes the clauses of a conditional construction are elliptical, meaning that they are missing elements that can be surmised from the context. In most cases, elliptical *if*-clauses (and sometimes even main clauses) are interpreted exactly like their full forms and seem to be reduced merely to avoid repetition. For instance, the following constructs illustrate the point: *I'll go, but not if John goes. If not, why not? If not now, then when?* However, there is a class of *if*-clauses that require other interpretations, since they are not conditionals per se, but rather illustrate the structures of concessive clauses. For instance, the following clauses are concessive and not conditional: *The Queen of England is happy, if not ecstatic. He spoke ungraciously, if not rudely. She ate many of the cakes, if not all. The salary was good, if not up to her expectations.*

Further interesting point about the construction of conditional sentences is the case of *inversion* which is used to make the sentence more emphatic. The following could serve as examples: *Should you see John, tell him I am here. Were you better prepared, you would sit for an exam now. Had you warned us before, we would have arrived earlier.* The placement of verbs at the beginning of a sentence produces more emphatic constructs that acquire additional emotional connotations through specific syntactic structures.

Scientific Framework of Syntax

Syntactic structures, or sentences, help humans to express thoughts, abstract and concrete notions and phenomena, desires, intentions, and goals. To put it differently, sentences reflect human cognitive processes, such as thinking, problem-solving, decision-making, and perhaps most importantly, creativity.

Therefore, syntax lies within the framework of science, namely that of cognitive science. It applies the scientific methods of gathering and observing data; of making generalizations based on the observed data; and thereafter, of developing hypotheses. All these steps are characteristics of scientific fields such as syntax, among many others.

Through innumerable sentences can be expressed an innumerable number of thoughts, ideas, and opinions that reflect human cognition. Observing these verbally structured cognitive processes enables scientists to make generalizations about human cognition, thinking, learning, memory, concentration, and the logical, coherent expression of one's ideas.

These data are gathered through observation of a vast range of syntactic structures uttered or written by humans in a huge number of instances. Thereafter, the method of grammaticality judgment is applied to distinguish coherent and well-structured sentences from those that are incoherent and ambiguous.

Through the analysis of syntactic structures, through their simplicities or complexities, the development and evolution of human cognition and human language can be traced over extended periods of time.

Therefore, syntax, as a scientific method, vividly reflects, analyzes, and generalizes human and linguistic evolutionary stages.

Transformational and Generative Grammar

The generation and transformation of syntactic structures into their numerous modifications was proposed by the linguist Noam Chomsky, who attributed the capacity of the production of innumerable sentences through a finite set of grammatical rules innate in human nature to acquire and use language. In his landmark study on *Syntactic Structures*, Chomsky suggests a model combining *phrase structure* and *grammatical transformations*, which has been demonstrably effective for syntactic analysis. The most significant activity in this respect is tracing the chains of sentence transformations and following the entire process of generating various syntactic structures by applying grammatical rules. Another significant Chomskyan contribution to linguistics is the concept of deep structure, as opposed

to surface structure, which enables more sophisticated ways of syntactic analysis.

Government and Binding

Within transformational and generative grammar, there exist several theories essential for syntactic analysis. Central to syntactic analysis are the theories of government and binding. *Binding theory* poses locality conditions on certain processes and related items, whereas the central notion of government theory is the relation between the head of a construction and categories dependent on it. *Theta* (θ) *theory* is concerned with the assignment of thematic roles such as agent-of-action (i.e., θ -roles). Binding theory is concerned with relations of anaphors, pronouns, names, and variables to possible antecedents. *Case theory* deals with assignment of abstract case and its morphological realization. *Control theory* determines the potential for reference of the abstract pronominal element. These subsystems are closely related in a variety of ways. For instance, binding and case theory can be developed within the framework of *government theory*. Furthermore, case and θ theory are closely interconnected. Through the interaction of these systems, many properties of particular languages can be accounted for. A great deal can be learned about Chomsky's notion of *universal grammar* (i.e., that structural rules of language are innate in humans) from the study of a language, if such study achieves sufficient depth to put forth principles that have explanatory force but are underdetermined by evidence available to the language learner. The study of closely related languages that differ in some clustering of properties is particularly valuable for identifying and clarifying parameters of universal grammar that permit variations in the proposed principles.

Syntax of Negation

Negative constructs present an especially interesting case for syntactic analysis, which mainly falls within government-and-binding framework. Negative structures and their development over the course of centuries bear significance for word-order alterations in sentences. The exclusion of

double negation in modern English is one such example of tracing developmental stages in language evolution. Negative constructs also play significant role in the comparative cross-language studies.

Statistical Analysis

In modern linguistics, statistical analysis has been widely used for measuring in quantitative terms the acceptability of various syntactic structures. Obtaining data for syntactic analysis has presented a special challenge to researchers. Sampling decisions have been particularly tough to make, since syntactic structures present a special case where the data need to be extracted from representatives of native speakers in order to evaluate the validity of the *grammaticality* of a construct. In syntax research, an interval scale of grammaticality is commonly used. Sentences are rated as grammatical, questionable, or ungrammatical. However, it has been observed in the study of sensory impressions that raters are more consistent with an open-ended rating scale than they are with category rating scales. So, in recent years, methods from the study of psychophysics (subjective impressions of physical properties of stimuli) have been adapted in the study of sentence acceptability. Hence, researchers are evaluating the *degrees of relative acceptability* of a sentence rather than grammaticality or ungrammaticality at its extreme forms. The main concern of researchers at this point is measuring the degree of word-order violations in various syntactic structures and accordingly judging the degrees of their acceptability. Statistical analysis is widely applied both in empirical and scientific frameworks of syntax.

SYSTEMS SCIENCE

Systems science is the ordered arrangement of knowledge whose domain of inquiry consists of *thinking*, *conceptualizing*, and *modeling* the behaviors of the real world in a systematic way. This entry discusses the fundamentals of systems science, including (a) the ways in which systems thinking represents the main characteristics of systems, (b) how system conceptualization has defined the basic concepts of systems, and (c) the role of systems modeling in providing the tools

that are used to create and test systematic experiments to simulate real-world behaviors.

Systems Thinking

Systems thinking is a perspective that considers events and structures as parts of a whole system that carries out a certain function, and which attempts ascribe meaning to systems based on their parts and on the interaction of these parts.

Construction of systems science begins with systems thinking and goes back to the early 1900s. In the 1920s, Ludwig von Bertalanffy developed the concept of *organismic biology* using a somewhat Darwinian approach. His views, however, did not attract significant attention from the scientific community. In 1937, Bertalanffy presented a report titled “The General Systems Theory (GST).” Although this report also failed to attract much attention at the time, it nevertheless has come to be recognized as one of the most important studies in the field of science. It was not until 1950 that Bertalanffy was able to publish his first article, in which he clarified and elaborated his thoughts regarding the GST.

During the 1954 meeting of the American Association for the Advancement of Science, a new society was founded by the biologists Bertalanffy, Kenneth Boulding, Ralph Gerard, James G. Miller, and Anatol Rapaport. This society was initially named the Society for the Advancement of General Systems Theory and later renamed as the Society for General Systems Research.

GST has its roots in the concept of *organismic biology* developed by Bertalanffy: In contrast to physical forces such as gravity and electricity, life cannot exist outside of individual entities known as *organisms*. Each organism is a system, and thus a dynamic order with its own interactions, parts, and processes.

Both organic and mechanical systems can be the subject of systems thinking. For example, the systems thinking used to describe the relationship between the energy spent and the distance covered by a lizard when it is jumping can similarly be used to describe the relationship between the fuel consumed by a car and its movement.

What matters in this context is not so much the similarity of the “objects” or “cases” being

considered but rather the similarity of processes. For example, the point that needs to be considered is the similarity between the exponential growth processes for money and the exponential growth processes of human populations. Therefore, in case money is placed on interest at a yearly rate of 7%, and in case a population similarly grows at a rate of 7% every year, both the sum placed on interest and the population in question will double in 10 years. When determining the behavior of a system, the structure of the system (the order and nature of the processes) is generally as important as its components.

In addition, both natural and artificial systems can be evaluated within the scope of systems thinking. For example, just as it is possible to explain the functioning of the human body by using systems thinking, so can the organization and functioning of a business also be explained by using systems thinking.

According to perspectives based on systems thinking, the structures that constitute living organisms are the result of interactions between parts that possess their own inherent characteristics. Thus, by defining these parts and their interactions, it becomes possible to understand the living organism. A component, or part, is an entity that has its own characteristics and which can become associated with other components/parts. When different parts come together or are brought together to perform a certain function, this results in the formation of a whole entity known as the *system*.

Systems also bear and reflect the characteristics of their parts. Depending on their function, they will also have their own inherent characteristics. Different systems can also be assembled together to form different and even more complex systems.

From this perspective, many of the entities encountered in our lives are systems. Entities that are not systems are referred to as *masses*. The main difference between masses and systems is the way in which they perform their functions. A mass is limited to its constituting parts. As such, the interactions between these parts do not create a special function. For example, masses of sand, water, or cement are formed by grains of sand, droplets of water, and grains of cement. However,

because these constituents do not have a particular function, the characteristics of masses will not change regardless of how many parts the initial masses are divided into. If one divides a sand pile into two parts, and then into four parts, one will obtain masses which, despite their smaller sizes, will have the same characteristics as the initial mass. On the other hand, if sand, water, and cement are brought together in correct proportions within a building system, the relationship between these parts will create not only a new function but also a new system. In such a case, dividing the resulting system into smaller parts will cause the system to lose its ability to fulfill its function. For this reason, *a system represents a whole that is more than the sum of its parts.*

The relationships between the parts that constitute a system are causal with regard to events and symbiotic with regard to structure. A causal relationship refers to the cause-and-effect relationship between the interacting parts. A causal relationship applies when, within the context of an event, a cause in one part of the system creates an effect at another part of the system. A symbiotic relationship refers to those cases when there is a mutual interdependence in the relationships of the different parts constituting the system. With regard to systems science, the basic principles that determine the characteristic of the relationships between the different parts are as follows:

1. The relationships are of a dynamic character: Relationships constantly evolve to the state in which the system's function can be best fulfilled.
2. The relationship between the different parts can involve the flow of materials, information, or energy. The same rules are applicable under different circumstances and conditions.
3. The relationships are sensitive to environmental changes.
4. Together, the system's relationships form a dynamic relationship.
5. The system relationships are based on cause-and-effect relationships.
6. Relationships indicate how one part can affect another part within the same system. For example, increasing urbanization leads to a decrease in agriculture. Excitement causes blood

pressure to rise. In system relationships, the first variable influences the second variable.

In such a relationship structure, it is possible to describe two different relationship groups. The first relationship group refers to the group of relationships between the parts that constitute the system. For systems, the first group relationships represent input–output relationships. All the values that systems require to fulfill their own functions are considered as inputs. On the other hand, the products obtained following the processes and functions of these systems represent the outputs.

Systems Concepts

Systems concepts are definitions of specific functions or parts of the systems. These definitions help us to understand the behaviors of the systems.

In case a system does not have an input–output relationship with its environment, this system is referred to as a *closed system*. Systems that have input–output relationships with their environment, on the other hand, are known as *open systems*. Within the scope of these relationships, the structure that exists between the inputs and outputs of the system will indicate whether the first group relationships are linear. To determine whether the relationships within this group are linear, two tests are performed:

- **Homogeneity test:** In case a change in one of the inputs of the system causes an equal change in the system's outputs, then the first group relationships of the system are considered to be *linear*.
- **Additivity test:** In case the sum of the effects of the two inputs is equal to the sum of the effects caused by these inputs through the system, the system is considered to exhibit a linear relationship. However, in case the sum of the effects of the two inputs is different from the sum of the effects caused by these inputs through the system, the system is considered to exhibit a *nonlinear* relationship.

Systems with fully linear relationships are known as *linear systems*, while systems without linear relationships are as *nonlinear systems*.

The other relationships of a system include the relationships between its own parts. In case the changes in the relationships between a system's parts result in predictable and definable changes in the system's behavior, the system is considered to display simple relationships. Systems with such relationships are known as *simple systems*. In case the changes in the relationships between a system's parts result in unpredictable and indefinable changes in the system's behavior, the system is considered to display complex relationships. Systems with such relationships are known as *complex systems*.

Ross Ashby's *law of requisite variety* demonstrated that a complex system can only be controlled by another system that possesses a mechanism of equal complexity. According to Ashby's approach, "only variety absorbs variety." More complex systems are more sensitive to their environments. The minimum variety necessary to perceive a complex environment is also determined to be a system's complexity. Social organizations are more complex than physical organizations/systems.

A system undergoes an adaptation process that depends on the structure and nature of the environment in which it is found. This structure is dynamic. As a result, part of the change observed in the system will stem from its efforts to adapt to the new environment, while the remaining changes will stem from the attitude and behavior of other systems. This interactive aspect of the environment is reminiscent of the processes that biological systems undergo. Within this structure, the survival efforts of systems are limited to their possible behaviors. The choices of a system within changing structures will determine its likelihood of surviving. These types of environments are called *fitness landscapes* and are very well known from the study of biological systems. For this reason, the first studies and definitions for fitness landscapes have been defined and developed many years ago (first by Herbert Spencer in 1864).

The fitness landscape is composed of the probabilities for different decisions that the organization might make during a change process. Stuart Kauffman previously demonstrated that this landscape could be defined by using the number

of these probabilities (N) and the connectivity of each choice (K). Kauffman's work thus allowed the fitness landscape model, which is also known as the *NK model*, to acquire a mathematical expression. Each choice probability has a corresponding fitness value. This value (which is the mean of all probabilities) describes the area in which a choice is located within the system and with respect to other choices (i.e., its distance and relationship to other choices). Kauffman defined the fitness landscape mainly for biological systems.

Self-organization increases when systems interact with their environments at the edge of chaos. The flexibility provided by self-organization renders it easier for successful organizations to constantly adapt to the changes in their environment. Three important mechanisms that allow systems to self-organize are identification, information, and relationships. A system formed by self-organization acquires certain characteristics and behaviors, as well as certain spontaneous properties.

In case a system is a closed system, its function (commonly understood as its reason for existence) will not be dependent or affected by its interactions with the environment. In other words, the system's functions will not be dependent on inputs and outputs. In such a system, the outputs will gradually decrease if the inputs remain the same. This, in turn, will cause the system's energy to constantly decrease. For this reason, closed systems eventually lose the qualities that allowed their constituent parts to remain together, which leads them to fall apart. This tendency of closed systems to fall apart is defined as *entropy*.

Entropy reflects the fact that the functions of systems are not associated with their environmental interactions and that they consequently experience a constant loss of energy that ultimately leads them to fall apart. Thus, to strengthen the bonds between the parts of a system, it is necessary to strengthen the relationship between its function and its inputs–outputs. As such, it is necessary to increase the inputs or the outputs relating to the function. The flow of energy that leads to an increase in the system's inputs or outputs is called *negative entropy*.

To be able to perform their functions in a sustainable manner, systems attempt to increase their

input–output relationships. This allows them to continue their existence—or to continue living. In this context, *living systems* are systems that can constantly develop negative entropy.

The efforts demonstrated by systems in order to increase their negative entropy are known as *adaptation*. Systems that can undergo change in order to develop their input and output relationships are called *adaptive systems*.

The relationships and interactions of systems in both groups are bidirectional. The fact that these relationships are bidirectional means that both the relationships between the system and its parts and the relationships between the system and its environment will have an effect on the system. These effects can reshape the behavior of the system with respect to its activities. This type of interaction is called *feeding*.

Feeding that stems from the relationship between the environment and the system is called *feedforward*. Feedforward involves an evaluation process that progresses from system inputs to system outputs (from backward to forward). Before beginning its functions, a system first attempts to obtain inputs from the environment that are suitable for its functions. This allows the system to shape itself according to future conditions when developing its functions.

Feeding that stems from the relationships between the system and its parts is called *feedback*. Feedback involves an evaluation of whether the system acts according to its functions through assessments that progress from the system's outputs to the system's inputs (from forward to backward).

In case a system function deviates from its previously determined goals, it becomes necessary to perform a correction in the inverse ratio and direction of the deviation. In case this correction increases/improves the function of the system, the feedback is described as *positive feedback*. In case this correction decreases/reduces the function of the system, the feedback is described as *negative feedback*.

Feedback allows systems to reach a state of equilibrium. An important feature of systems that can reach equilibrium is their ability to react actively to change. Most living systems continue to function and to use energy even when they are not required to display any reactions. Mechanical systems can be entirely deactivated for a certain

period of time and then be reactivated. The same type of behavior is also observed in certain simple life forms. Certain plant roots can wait for years until suitable conditions for growth become available, while certain microorganisms can be frozen and then reanimated. However, most organisms need to remain active in order to stay alive. In other words, they will inevitably die if they become inactive.

As a general rule, a more complex system will also have a higher level of internal activity. This increases the likelihood of the system to trigger change in its environment. Complex systems spend more energy to process information and to ensure their continuity. This same rule is also applicable for social systems. For example, while a club may be easily closed and then reopened, doing so for a company is far more difficult. A society, on the other hand, needs to be constantly active and to ensure its own continuity.

The behavior of systems is largely determined by their feedback reactions. This phenomenon is called the *reaction time*. The functioning of a simple thermostat/oven involves a long reaction time, since air conveys heat from the oven to the thermostat at a relatively slow rate. Social systems also have generally long reaction times. If the reaction time is too slow, external changes will take place at a comparatively faster rate, such that the system will be unable to respond. In addition to this, the reaction time is generally the same as the basic tempo, or the “shot” of the system (the minimum interval between the oscillations of the feedback process). By watching these oscillations and estimating the time interval, it is possible to determine the minimum time interval that a certain system may overcome.

Forming the decisions of a system also requires its identity to be formed/created. The property of a system that allows sufficient free movement for the formation of an identity is referred to as its *viability*.

Systems Models

Systems models are tools that are representations of the real world in different perspectives. There are different types of systems models based on their perspectives. Some of them are explained briefly as follows.

Complex Adaptive Systems (CAS) Model

H. John Holland argued that integrating systemic complexity and environmental complexity with one another could only be achieved on the basis of the inherent abilities of the system. Foremost among these system abilities is the adaptation skill. For this reason, such systems are referred to as CAS. The general structure of the CAS is framed according to seven basic laws. Four of these laws describe the characteristics of the CAS. These are the laws on aggregation, nonlinearity, flows, and diversity. The other three laws describe the mechanisms of the system, which are tagging, internal models/schemas, and building blocks. CASes can be described as the fundamental elements of the concept of complexity. CASes are self-organizing systems. Self-organizing systems tend to organize themselves by using energy, materials, and feedback from their internal and external environments. Similar to traffic, crowdedness, and organization, self-organization is also a characteristic of a multicomponent system. Self-administering teams within organizations represent examples of self-organization.

Social Systems Model

Luhmann has contributed to systems science in the area of sociology by constructing the social systems model. Luhmann's views were largely based on the structural functional systems theory, whose foundations were established by Talcott Parsons. Parsons associates the existence of a system to its function. For the continuity of the function, systems establish their own optimal balances. To ensure balance, it is important to closely follow the system's relationships with the environment and to ensure that the parts of the system remain together as a whole. It is for this reason that institutions are necessary. With this type of structure, all events that occur within society are the result of interactions between the actors. The action that forms the basis of this interaction harbors four basic elements/aspects: adaptation, goal access, integration, and implicit pattern formation.

Luhmann systems are divided into two basic groups, which are the autopoietic and the

allopoietic groups. *Autopoietic group systems* are systems that undergo structural changes of their own when establishing a dynamic balance. These include social (interaction, organization, and social) systems as well as psychological systems. *Allopoietic systems*, on the other hand, refer to machines and organisms.

System Dynamics Model

Toward the end of the 1950s, Jay W. Forrester developed a new theory based on concepts relating to feedback, work evaluation, organizational and social relationships, and the structural changes associated with these relationships. The theory involved the modeling of mathematical changes in structural movements.

The rationale of the system dynamics model is based on the view that the movements or changes triggered in real structures will actually consist of small-scale movements, while complex situations mainly stem from relationships and interactions between the elements of the system. The interaction of all effective system elements on any structure will lead to complexity. It is believed that this complexity can be understood through the analysis of feedback structures that are inherent to all relationships. For this reason, feedback structures play a key role for understanding complexity.

In this context, the graphic illustration and description of the system dynamics model indicates that this model is very similar to GST. In addition to being easy to use, the system dynamics model allows the modeling of nonlinear relationships within an organization. It thus represents a tool that can be easily used and understood by those in decision-making positions. Although models developed using system dynamics involve numerous elements and relationships, they do not take much time to prepare and are quite descriptive.

The time-dependent change observed in the elements or variables that constitute a system represent the behavior of a system. The behavior of a system is intrinsic, dependent on the baseline, and nonlinear. Systems demonstrate their behavior under the influence of their own structure and elements. This behavior is displayed within the limits and effects of the system's structure. Based on this consideration, it is possible to show that a system's

structure also determines the behavior of the system. Thus, system dynamics identifies the relationship between a system's behavior and the structure that is at the source of this behavior. In other words, system dynamics evaluates how the structure of a physical, biological, or literary system shapes the displayed behavior of the system. For example, by identifying the structure of an ecological system, system dynamics allows the time-dependent behavior of this system to be effectively analyzed.

Viable Systems Model

Viable systems modeling was constructed by Stafford Beer. It represents a cybernetic approach to systems science. According to Beer, freedom does not define a state that is distant or dissociated from the other entities in the environment. For example, what defines a university is the education it provides and the research it performs. Without these functions, an institution would not be considered a university. As such, all of the units, faculties, departments, centers, and so on, that provide education, conduct research, and bring life to the university through their products/outputs can be considered living systems. The other structures within the university such as dormitories, dining halls, and councils and committees, on the other hand, are not living systems. For a system to be considered a living system, it must be able to interact in autonomously with its environment. Autonomy allows a system to make decisions based on its own abilities/capacities. Viable systems have mission statements, as well as an accountabilities within the scope of the functions they carry out in accordance with the policies and strategies of the larger entity of which they are part. The continued viability of systems is achieved by two main mechanisms: (1) cohesion and (2) adaptation. The cohesion mechanism aims to ensure that the goals and interests of the independent units within the main system are in agreement with the policies, strategies, goals, and interests of the main system and that the competitive strength of these units are reinforced. The adaptation mechanism, on the other hand, aims to ensure that the system is able to adapt in a timely manner to any changes that might occur in the external environment. In addition to adaptation,

learning, development, and evolution are considered among the basic dynamics of the concept of viability. It would not be possible to achieve evolution without first achieving adaptation; to achieve adaptation without first achieving learning, and to achieve learning without first achieving equilibrium.

Causal Relations Model

Causal relations models are system models that represent systems behavior with causal relations. Causal relations do not refer to a ranking but to influences on system functions. The relationships within the system are not linear but circular. The circular definitions of system behavior is called a "structure." Different real-world behaviors can be modeled with the same structure. In this perspective, it is accepted that structures define the behaviors.

A systems structure can be constructed according to two different kinds of loops. The first kind of loops are *reinforcing loops*. Such loops generate either a continuous increase or decrease in systems behavior. For example, the number of customers is increased by increasing the investment in products or services. Increase in number of customers leads to increase in revenues, which leads to increase in investments. The other type of loops are *balancing loops*. In balancing loops, at least one (or in odd numbers of) relation is a negative relation. For example, if the positive perception of a service quality is increased, more people are attracted, thereby creating a queue. While the number of the people waiting in the queue is increasing, the waiting time is increased. Increase in waiting time leads to decrease in the perceived service quality. Decrease in perception about service quality leads to decrease in the number of the customers attracted. This loop models a systems behavior that is opposite to the initial behavior.

In causal relations models, it is accepted that delays in relations and mental models of the actors can create the changes in systems behaviors. Mental models that cause changes in relations are represented by clouds. Delays are represented by two parallel lines.

TAXONOMY

Taxonomy is the science of classification and may refer to either the process or the product of a classification system. Most widely used in the biological sciences, taxonomy can refer to any controlled, hierarchical vocabulary attempting to achieve a standardized classification or naming system. Taxonomy, as a conceptual tool, has allowed widespread scientific and technical vocabulary to transcend regional nomenclature and folk knowledges by standardizing the use and relationships of terms. It also can refer to a methodological approach to classification, specifically in botany and zoology. The most widely recognized taxonomic system in the sciences, within botany and zoology, is based on the work of the Swedish botanist Carl von Linné (1707–1778), commonly known as Carolus Linnaeus. He is generally considered the father of modern taxonomy, though many before him had sought to form a standard classification system.

Taxonomies have been studied as tools for conceptual categorization of the world. Folk taxonomies have been of particular interest in psychology and anthropology as conceptual knowledge of things is expressed in cultural systems. While the study of folk knowledge and folk taxonomies are of particular interest in the social sciences about how people act, believe, or think through folk classifications, taxonomy in the biological sciences is more of an active process of classification. Thus, taxonomy can also refer to a conceptual tool of

the mind, a cultural tool of an ethnolinguistic group, or on the level of an internationally standardization project.

Taxonomy as Conceptual Categories

Taxonomies, in the broadest sense, are systems of conceptual categories. They are mental and cultural tools used to help humans understand the world around them. All groups of people have some system of classification of things, and the way things are classified can indicate much about beliefs and values. Anthropologists and linguists, among others in the social sciences, may collect the terms and relationships from a particular ethnolinguistic group. Although the categories may not be scientifically defined, they present a particular view of the world from the perspective of the people within the group. These taxonomies, or classification systems, help to identify the names, categories, and relationships of terms in a particular language. For example, the difference between astrology and astronomy entails a difference in the classification of the celestial bodies. Astrology is a folk system observing the stars and planets based on their spatial relationships from the viewpoint of the observer (i.e., constellations). Although these categories do not match the modern scientific categories within astronomy, historically they have provided some useful information by way of mapping out the relationships of visible celestial bodies through a different, although internally consistent, taxonomy.

Taxonomy as a Controlled Vocabulary

Natural language lacks the specificity for large-scale technical and scientific work. Ambiguity is introduced through synonyms, homophones, and colloquialisms, thus providing a potential threat to specific and technical reference. A common example in botany is that of the European Mountain Ash. Although the common name would seem to indicate its relationship to the true ash tree, they are actually not so similar. The scientific name for the Mountain Ash is *Sorbus aucuparia*, from the genus *Sorbus*, among the rose family. A true ash tree is from the genus *Fraxinus*, from among the olive or lilac family. Although the common name bears striking similarity, the plants are actually distant in the taxonomic hierarchy. Thus, to be specific in scientific classification, a taxonomy in which the names of plants do not bear overlap between categories is preferred.

A taxonomy is an attempt to create a standard classification system for a particular domain in which each term, or *taxon* (plural: *taxa*), would be an individual, specific term hierarchically related to other terms. Taxonomies may be intended to standardize classifications and nomenclature within institutions, throughout a particular industry or field, or even to create the ability for global scientific collaboration. Sometimes, a governing body may be instituted to control the vocabulary to make sure it is standardized, though often the taxonomy is set at a particular point in time and is extended or built upon more organically.

As a standardized vocabulary, a taxonomy is a logical device not always intending to be an empirically defined categorization of the world as such. The limits of language, and the specific use of words-for-things, prevent taxonomies from being cultural maps of the world and rather should be seen as logical categorization processes. Similar to a thesaurus, a taxonomy seeks to control for ambiguity, eliminate synonyms, and to display hierarchical relationships. However, unlike a thesaurus, the taxonomy does not draw lateral or associative relationships between terms. By controlling the vocabulary in such a way, the process of taxonomy should eliminate ambiguous terms and explicitly show hierarchical relationships. The result is a specific and unambiguous mapping of terms.

Biological Taxonomy

Taxonomy in the biological sciences has been around for millennia. As early as Aristotle (384–322 B.C.E.) and his successor Theophrastus, one can see a clearly ordered vocabulary attempting to differentiate between species of plants and animals. Based on observations, they described in detail similarities among like specimens. Their approach was to inductively reason that which was an organism's *nature*, or that which is necessary for that organism to be identified as that organism, through observing many specimens of that organism. Aristotle organized his system from simple to complex forms of life. Aristotle and other early empirical scientists did not have the scientific tools, such as the microscope, to observe minute forms of species. Still, Aristotle's system laid the basis for taxonomic work until the 19th century, when scientists began to favor an evolutionary approach to classification as opposed to a natural approach.

As biological and medical sciences grew in the 1500s and universities began to revive a focus on studying nature, Aristotle's system was built upon or modified. Works on plants and animals showed little consistency of nomenclature, and often many different names were ascribed to a particular organism so as to describe it; names were not standardized. Generally working from Aristotle's system, Linnaeus developed a system with two kingdoms (one for plants and one for animals) and several ranks. Linnaeus, whose works were extremely detailed in description of the nature of organisms, also began to standardize names for plants and animals by developing a two-name convention system. The nomenclature, then, was separated from the taxonomy, so as to achieve a standard system. This system still remains in use today.

Since Linnaeus, the science of taxonomy has continued to develop. Two major developments have occurred. The first was an extension of the system by applying different ranks and nomenclature. The second reformed the way taxonomy was done on a more basic level, that of phylogenetic development rather than natural affinity.

The systems that developed out of the work of Linnaeus continued to shift on the basis of what was observed in the world. At present, for example,

there are two major competing systems, the domain system and the kingdom system. The distinction centers on whether all organisms can be categorized into three domains (Archaea, Eubacteria, and Eukaryota) developed by the microbiologist and physicist Carl Woese in the 1990s, or simply the five kingdoms (Monera, Protista, Fungi, Plantae, and Animalia) proposed by Robert H. Whittaker in 1969. The rank of domain was added chiefly to accommodate the discovery of the unique features of Archaea, which were difficult to categorize into one of the five kingdoms and were distinct enough to perhaps require a new hierarchical category. Eight major ranks have also been developed and generally accepted (domain, kingdom, phylum, class, order, family, genus, and species).

The second major development since Linnaeus speaks to the onset of a new worldview: that of evolutionary biology. Taxonomy is not simply a classification of *like* and *unlike* organisms but also presents a theory of the relationships between them. Whereas previous taxonomists had assumed that all living things had a nature, and thus should be categorized based on inductive observation, with the understanding of evolution, the phylogenetic development of organisms was emphasized above the direct observation. Thus, reference to the fossil record became a major strategy for the classification of species. This ultimately shifted the assignment and interpretation of classifications. Hierarchical relationships could be understood not only as a taxonomy of natural features but also to some extent a description of development.

Process of Taxonomic Classification

The approach to taxonomic studies is not necessarily standardized, but it requires first and foremost the collection of suitable specimens. Once one can collect a quality specimen of a particular type of plant or animal and then begin to compare it among the variation that already exists, detailed notes and descriptions are made to compare and contrast with what is known. If one suspects the specimen is a new or undocumented species, then a suitable name, derived from the internationally recognized codes, would be applied. Once a specimen is documented and named, it must be situated within the existing categorization structure.

The existing classifications may be revised if the specimen lends new evidence that seems to contradict the current classifications. This process, though not a standard set of procedures, is the general process of doing taxonomic work.

International and Universal Coding Systems

In order to create a taxonomy that is broadly applicable enough to be used globally, there must be some way to regulate the language. International universal codes have been published for such purposes. These codes define a standard nomenclature and classification system, but the content, of course, is left to taxonomists who apply the system to real specimens.

The International Association for Plant Taxonomy, for example, publishes their *International Code of Nomenclature for Algae, Fungi, and Plants*. This document dictates specific word endings for ranks, such as *-phyta* for any plant phylum. As such, this document serves as a control to allow for the naming, classification, and cross-referencing all plant, algae, and fungi organisms. These types of universal codes allow for the standardization of a taxonomy that incorporates methodological rigor and peer review of data. They also ensure the standardization of naming. As consistent with the long conventional history rooted in Linnaeus, the naming of any species will be unique, including a binominal name made up of the genus and species name. Sometimes, it is important to distinguish the subspecies, as if one was referring to regional differences in a species of tree. In these instances, a trinomial name consisting of the genus, species, and subspecies would be used.

Examples of Taxonomic Names

The standard classification of species, as noted above, usually contains eight major ranks. This allows for hierarchical specificity. However, the name of a particular species usually contains only the genus and the species name. Below is the taxonomy of the modern human, the cougar, the mountain ash from the example above, and the white ash to show the hierarchical distinction.

Table 1 Examples of Official Nomenclature

Rank	Modern human	Cougar	Mountain ash	White ash
Kingdom	Animalia	Animalia	Plantae	Plantae
Phylum	Chordata	Chordata	Magnoliophyta	Magnoliophyta
Class	Mammalia	Mammalia	Magnoliopsida	Magnoliopsida
Order	Primates	Carnivora	Rosales	Scrophulariales
Family	Hominidae	Felidae	Rosaceae	Oleaceae
Genus	<i>Homo</i>	<i>Puma</i>	<i>Sorbus</i>	<i>Fraxinus</i>
Species	<i>H. sapiens</i>	<i>P. concolor</i>	<i>S. aucuparia</i>	<i>F. americana</i>
Subspecies	<i>H. s. sapiens</i>			

Each scientific name is binomial, though sometimes the trinomial name may be used. For example, modern humans are *Homo sapiens*, but in order to differentiate them from their immediate predecessors, the trinomial name *Homo sapiens sapiens* is used. A predecessor, though the same species as modern man, has been distinguished through fossils in Eastern Africa and named *Homo sapiens idaltu*. The distinction is still up for debate as fossil records are updated.

The species and genus name make up the official nomenclature. Some extend back to Linnaeus's classifications.

As can be seen from the examples in Table 1, the scientific specificity of each species allows botanists and zoologists to cross-reference species with their hierarchical relatives. Any organism would be identified through this taxonomy.

Other Applications of Taxonomy

Among the various taxonomies that are used on small and large scales, some have become quite widely accepted. One that has been very influential in education is the taxonomy of learning domains, developed by the educational psychologist Benjamin Bloom. Bloom's taxonomy of the cognitive domain was part of a larger work that included three categories that could be useful in training or education: *cognitive*, *affective*, and *psychomotor*. Within these categories, different abilities or skills can be identified. Within the cognitive domain, for example, six categories may be identified. These have been extended and revised to include six verbal categories: *creating*,

evaluating, *analyzing*, *applying*, *understanding*, and *remembering*. This taxonomy is broadly applied in education, as many teachers are instructed to write lesson plans that focus on more than a single domain and to ask questions to students that focus on different cognitive domains. Thus, the taxonomy has provided a sort of template to think about cognition in the classroom, in assessments, and in education more generally.

Abraham Maslow, a noted psychologist, developed another widely used taxonomy. His hierarchical schema of what motivates humans can be understood as a taxonomy. It categorizes the needs of humans from the most fundamental, such as breathing and eating, to more complex needs for self-actualization. This theory is highly influential in psychology, although it has drawn some criticism on the grounds of its empirical underpinnings. Nonetheless, this hierarchy, as with many different developmental theories, attempts to taxonomize human development by standardizing the way we categorize its aspects.

THEORY CHANGE

Science strives to develop theories that explain its subject matter of *reality*. When a theory passes severe tests, when its scope can be expanded, then scientific knowledge-seeking is deemed to be successful. But if a theory changes or is even replaced by a new theory, if it emerges that a particular theory has possibly been wrong, then mistrust may attach to the scientific enterprise. Theory change has thus become a double-edged sword at the heart of the self-reflexivity of science that has engendered an intense and ongoing debate in the philosophy of science. This entry traces the origins and emergence of the shift from an understanding of theory as logical analysis to one that takes into account the embeddedness of knowledge in history. Among the key topics covered are 20th-century developments such as non-Euclidean geometry, relativity, quantum mechanics, logical empiricism,

and critical rationalism, and the conception of theory change as radical shift as opposed to an incremental rational correction guided by logical rules. The contribution of societal, extrascientific factors, the concept of paradigms, and the contribution of experimental and cognitive practices are described and explained.

In what follows, we will examine how theory change, on the one hand, emphasizes the *historicity* of science. A historical product can change, and such change implies the transformation of a given *worldview* into a new one. A coherent system of *seeing* the subject matter of a scientific discipline is replaced by a different system. Theory change rejects the commonsense view of knowledge-seeking as pure accumulation of facts. Not only single elements of knowledge but the whole picture can change. Instead of comprehending science as a cumulative enterprise, theory change therefore emphasizes the active side of science: theory as something that is constructed. Consequently, scientists cannot only be concerned about the collection of facts and about how their discoveries should be organized under a given system of thought; scientists must also explore why and how new theories arise that shed new light on their subject matter. In this sense, theory change has raised previously unasked but nonetheless important questions. On the other hand, at the same time, the very same idea has also brought new doubts into science, the seed of relativism. That is, theory change calls into question the *rationality* of science by asking to what extent theories, which are only temporarily valid because they can possibly change, can still be considered objective.

It is interesting to see that theory change became a theme of discussion in the philosophy of science only at a relatively late date. It did not receive any attention at all in the first half of the 20th century. In the same package as related concepts such as scientific change and conceptual change, theory change was first abruptly and intensively discussed only in the 1960s but subsequently moved up the agenda of philosophy of science to become one of its most central and important themes in the second half of the 20th century.

For this reason, it is important to see, first, why and how in the middle of the 20th century an established understanding of theory was suddenly and successfully replaced by a new one.

The notion of scientific theory as a finished product that can be rationally reconstructed by means of *logic* was replaced by an understanding of theory as a *historical product* of human activity. The result was that the focus moved from theory as a static given to the constant possibility of theory change. Second, the terms and problems of the new understanding of theory change as a *radical shift*—a concept introduced first and foremost by Thomas S. Kuhn—have to be analyzed. Third, it will further be interesting to learn which new questions this has subsequently raised and which new answers have been given, by examining recent approaches that focus on the experimental and cognitive *practices* in the *process* of theory change.

From Logical Analysis to Historical Change

The conflictual understanding of theory as either a logical form or as historically changing first featured in the debate between the German early modern philosophers Immanuel Kant and Georg W. F. Hegel. When Hegel criticized Kant's epistemology in the early 19th century, the same problem was already at stake. Kant had powerfully articulated the constructionist idea of modern thinking that knowledge is a human product. While attempting to provide a philosophical foundation for Newtonian physics, Kant reasoned that the scientific understanding of the world cannot be *anchored* in empirical sensations or perceptions. He rejected the empiricist belief that knowledge can be acquired by simply aggregating experiences. In contrast, he postulated that knowledge is shaped by cognitive structures. Kant claimed that forms of intuition (space and time) and categories (such as substance or causality) are transcendental forms of a logical subject that must be assumed for understanding the acquisition of knowledge. Accordingly, knowledge is possible only within a distinctive frame of forms and categories. In short, Kant defends the priority of concepts over facts. Theory gives form and shape to reality, which for Kant is otherwise chaotic. Because the knowledge about the world is mediated by logical categories, Kant's approach did not yet raise the problem of relativism. For Kant, the objectivity of knowledge can still be

justified insofar as theory, the frame of reference, is anchored in transcendental structures of the knowing mind that are permanent and universal. Hegel, and after him other thinkers of the 19th century, rejected precisely the idea of any form of eternal truths that are immune to historical change. For Hegel, science cannot be based on transhistorical forms of knowledge. It cannot be based on a logical subject. On the one hand, Hegel shares with Kant the idea that knowledge is constructed via a categorical framework. On the other, and in contrast to Kant, Hegel historicizes this framework. He *de-transcendentalizes* the knowing mind—Kant's logical forms and categories—by locating reason in historical time and social space. In this sense, Hegel introduced history to epistemological analysis.

In sum, Kant and Hegel both stress the importance of theory in the construction of knowledge. However, whereas Kant still assumes a static world by claiming the dependence of thought on intuition, Hegel's phenomenology of different forms of knowledge emphasizes the embeddedness of knowledge in history. At the turn of the 19th century, Hegel introduced the idea of change to the understanding of theory: Even theories are historical entities; they are revisable. Theories change in history.

By the early 20th century, Hegel's influence had waned and Kant's atemporal philosophy had been strongly undermined, ironically by a factual, that is, historical theory change in science. The invention of non-Euclidean geometry in the 19th century and the uncertainty principle in quantum mechanics in the early 20th century required a revision of Kant's foundationalist principle of the a priori limits of scientific knowledge. In Kant's time, the worldview of a Newtonian clockwork mechanism underlay the scientific understanding of the universe. In Newtonian physics, the Euclidean metric appeared unshakeable. It was an axiom that provided a priori knowledge about the relations between space points, that is, about the structure of space. Kant accordingly supposed Euclidean geometry to be the repository of a priori truths that scientists impose on what they perceive. Since the emergence of non-Euclidean geometries in the 19th century and Albert Einstein's theory of relativity in the early 20th century, declaring that

physical truth is relative to geometric form, the actual geometry of the scientific worldview is no longer Euclidean. Accordingly, the dominant philosophy of science of the first half of the 20th century—logical empiricism—which framed the debate for several decades and was strongly rooted in the relativistic and quantum revolution in physics—could also no longer ground science in a priori truths about the natural world. The logical empiricists of the Vienna and Berlin Circles of the 1920s and early 1930s therefore shifted the primary focus from the quest for epistemological truths grounded in metaphysics to grounding epistemology in scientific methodology itself. Two strategies became central: an emphasis on empirical evidence and the application of logical analysis. First, only what is immediately given by the senses can be known for certain. No knowledge is immune from revision in the light of experience. Correspondingly, the limits for the content of science are set. Only *empirical statements* can be relevant. Unobservables are either deleted from the scientific agenda or they must be associated with terms for observables. Consequently, the manifesto of the Vienna Circle group proclaimed that any term in science must be ascertainable by stepwise reduction to basic terms of sensory experience. Besides propositions that express mathematical or logical truths, there are either observation statements or propositions that are meaningless because there is no observational evidence for them. Furthermore, observational facts, such as the existence of things of all kinds or experimentally observed correlations between variables, are differentiated from their theoretical interpretations, for instance, the concept of a gravitational force or the kinetic theory of gases. Facts and theories are sharply distinguished. If theory is necessary at all, it is secondary to the facts, given that the primary aim of the logical empiricist methodology is to base science on a nontheoretical, observational language. Second, in order to further keep all forms of metaphysics out of science, the only legitimate method to be applied to the hierarchical order of terms is *logical analysis*, that is, movement from elementary or protocol statements on the lowest level of actual experience to further statements via a controlled procedure. For Rudolf Carnap and other Vienna Circle thinkers, *inductive logic* guides the path from the most basic empirical statement of

immediate sense-data (*this tomato is red*) to other statements, such as empirical generalizations (*tomatoes are red*). Any hypothesis such as *tomatoes are red* can thus be true or false, but it cannot be meaningless; it will be either confirmed or invalidated by an accumulation of basic protocol sentences. Accordingly, theoretical terms such as *electron* do not refer to tiny particles but to logical constructions based on experiences. Both strategies—the reduction of theoretical interpretations to records of experience and the corresponding emphasis on logical analysis—had drastic consequences for the understanding of the possibility of theory change. Attracted by the rigor and clarity of mathematical logic, the attention of the logical empiricists was drawn away from change and directed at atemporal components of the scientific toolbox such as laws and confirmation. If theory change is a useful concept at all, it has to be understood as an accumulative process because the basics of science, the empirical statements, do not change. Generally speaking, science is the accumulation of empirically certified truths. Theories that replace each other are therefore also linked to each other. Any former theory can be reduced to a succeeding theory; that is, the former can be considered a special case of the latter. Science is continuously growing, step by step. There is progress in science, with each successive stage being more stable than its predecessors.

This view, based on the strict separation of the logical and the historical, was further supported by a widely accepted and very influential distinction made by Hans Reichenbach, who was the founder of the Berlin group of logical empiricists. Reichenbach distinguished between two realms of the scientific enterprise, placing them strongly in opposition to one another: the context of discovery and the context of justification. The latter refers to the logical analysis of scientific knowledge, while the former regards questions concerning the origin or generation of scientific ideas. Whereas all issues around the question as to how scientists arrive at their knowledge claims are therefore considered to be tasks for psychology, sociology, and history, the proper domain of the philosophy of science, according to Reichenbach's distinction, is the epistemic status of a claim, that is, the evaluation of scientific knowledge. Philosophy of science thus does not consider real

processes of knowledge acquisition. Instead, the task of epistemology is to evaluate the correctness of knowledge claims by arranging them in a consistent system, that is, the legitimacy of the reasons, arguments, rules and standards behind the empirical testing, and thus the confirmation or disconfirmation of knowledge claims will be considered. By contrasting the context of discovery and the context of justification of knowledge, it is obvious that, for example, a discussion about how views on the structure of space are acquired cannot help to ascertain whether Euclidean or non-Euclidean geometry of space is more justifiable. Following the neo-Kantian distinction between genesis and validity, logical empiricism separated logic from history. Instead of being interested in the diachronic dimension of theory change, the dominant approach in the philosophy of science in the first part of the 20th century focused on the synchronous investigation of the finished products of scientific research, defined as the mathematical and logical structure of (mainly) physical knowledge.

It is interesting to see to what extent the work of another influential philosopher of science, Karl R. Popper, who founded critical rationalism, the second major professional philosophy of science in the 20th century after the logical empiricist movement, supported or undermined this established view. Although Popper studied and received his PhD in the late 1920s in Vienna, he was never invited to become a member of the Viennese group of logical empiricists. On the one hand, both the logical empiricist and the Popperian approaches claimed that discovery has no place in the logic of science. That is, according to Popper, it is simply irrelevant to the logical analysis of scientific knowledge on how new ideas are received or created. On the other hand, although sharing with the empiricists the emphasis on experience, the view that theories can only be called scientific if their validity can be asserted in the light of observation or experiment, Popper also strongly deviated from the logical empiricist focus on verification in scientific methodology. For Popper, science does not begin with observations, perceptions, or *brute facts*. For this thinker, science begins with problems. Popper sees science as a problem-solving enterprise. Experience cannot determine theory and thus science cannot infer

theory from observational statements. It cannot inductively arrive at generalizable universal propositions because science does not proceed inductively but deductively. First, a new theory will be logically analyzed; its internal consistency will be tested. Then the theory in question will be compared to existing theories. If it does not promise greater empirical depth than its forerunner, it will not be adopted. If it promises to solve previously unsolvable problems, it will be adopted. Finally, the crucial step is its empirical testing. Theories contain logical and empirical elements. More specifically, theories must be operationalized so as to suggest hypotheses in circumscribed research areas. Hypotheses guide observations, where observations refer to perceptions. In other words, science does not begin with perceptions. Perceptions are actively planned and prepared through observations, which themselves are also selective; they are always preceded by something theoretical: questions, problems, or hypotheses. Popper's *searchlight* model of knowledge acquisition therefore explicitly opposes the *bucket theory* of knowledge, as he termed the empiricist approach. Science does not proceed by collecting facts; science proceeds by testing the empirical application of conclusions derived from theories. If a theory stands the test, it can be maintained. If it does not stand up to the attempt to refute it, it has to be abandoned. For Popper, therefore, falsifiability, not inductive verification, demarcates science from nonscience. The idea that all knowledge is provisional makes science a fallible enterprise. Scientific theories cannot be proved, they can either be provisionally confirmed or conclusively refuted. Although the growth of knowledge in science can accordingly no longer be understood as a cumulative process but must be seen as an endless procedure of error elimination, for Popper's theory change in science nevertheless involves theoretical progress because a newer theory must simply have greater empirical content than its predecessor. For example, the gravitational theory of Isaac Newton has had greater generality than Johannes Kepler's and Galileo Galilei's laws of motion. According to Popper, the former cannot be considered as having been inductively inferred from the latter theories. On the other hand, the explanatory scope of Newton's theory not only included both Kepler's kinematics of celestial

motion and Galileo's kinematics of terrestrial motion; Newton's dynamics also provided a numerical measure that was close to, but different from, the theories of Kepler and Galileo. The same then applies to the replacement of Newton's theory by Einstein's theory of relativity in the early 20th century: Einstein's theory cannot be inferred inductively from Newton's; the two can be compared only by deductively testing them empirically and by demonstrating that one explains more than the other.

For the logical empiricists, theory change was not a matter of concern. They saw the body of knowledge as continually growing and theories as nothing more than snapshots in an ongoing learning process. For Popper, in contrast, theory change is no longer a cumulative process. It is a trial-and-error process with the objective of error elimination. But despite the strong theoretical conflicts between the two philosophies of science that were dominant in the 20th century until the 1960s, they also shared certain characteristics. On the one hand, they differ regarding the primacy of perception versus selective observation and on the role of induction versus the deductive testing of theories' scientific methodology. On the other hand, they share the emphasis on logical analysis. In both approaches, it is the rigor and clarity of a formal method that guarantees continuity and intersubjective validity. For both, science is a rational enterprise that advances by increasing approximation to truth. Although Popperians presuppose the fallibility of theories, for them falsification qualifies as the logical technique guaranteeing that any current theory can be provisionally maintained as the theory of greater empirical depth than its predecessors, that is, as the best available theory—until it is falsified. The critical rationalist method thus invites theory change as a change toward a *better* theory, which is distinguished by its capacity to solve more problems in the domain of the scientist than competing theories do.

For both methodologies, theory change is still under rational control. Logical empiricism and critical rationalism both share a general *logical* approach insofar as for the latter the logic of justification lies in falsification. They do not yet regard theories as historical entities that can be replaced by completely different theories for contingent historical reasons. By contrast, the

consideration of theories as historically given invites a new understanding of theory change. The new view takes into account the possibility of the subject matter of the scientific investigation also shifting in the process whereby one theory is replaced by a newer one. If this is so, if even the meaning of terms can accordingly change from one theory to its successor, then theory change implies a radical discontinuity in the development of knowledge.

Theory Change as Radical Shift

If theory change implies a radical shift as opposed to an incremental rational correction guided by logical rules, then a succeeding theory will no longer be understood as an improved version of the same theory but as a radically new theory. Examples are Newton's notion of gravity, Maxwell's dynamic theory of the electromagnetic field, Mendel's theory of genetics, and Einstein's theory of special relativity, all of which marked a deep transformation in the scientific understanding of nature.

To introduce the possibility of theory change as historical project in this radical new sense, new philosophical sources became important in the mid-20th century. Ludwig Wittgenstein's theory of meaning provided the main philosophical toolbox in this context. For Wittgenstein, meaning is not a separate entity. It is neither a mental image nor does it represent some object in the world. The meaning of a word depends on the uses made of it in various activities of human life when the users of a language are exposed to actual situations in which they must apply the word appropriately according to the rules and grammar of language. Understanding meaning in this way, not as a given entity but as a product of an actual *game*, that is, as a relational result, will be helpful for further understanding the arguments made against the philosophy of science mainstream in the mid-20th century. The attack that rang the knell for empiricism and the associated gradual interpretation of theory change was finally carried out by Thomas S. Kuhn's epoch-making book *The Structure of Scientific Revolutions*. The aforementioned arguments by other authors, however, prepared the ground for Kuhn's intervention. Basically, there were two complementary arguments.

First, in the late 1950s, the thesis of *theory-ladenness of observation* simply denied the existence of theory-neutral data. On the one hand, this thesis argues, theoretical presuppositions held by the investigator affect even perception. When a Ptolemaic believer in the Earth-centered universe and a Copernican believer in the sun-centered universe are watching a sunset, they see different things. The Ptolemaean sees the Earth to be stationary and the sun to be falling, whereas the Copernican sees a moving horizon and a fixed sun. Accordingly, people, not eyes, are seeing, as Norwood Russell Hanson, one of the authors who elaborated the thesis, concisely summarized it; and so for Hanson, even seeing is a theory-laden undertaking. Beyond perception conditioned by background assumptions, on the other hand, there is another version of theory-ladenness, namely, semantic theory-ladenness. According to the latter view (and as for Wittgenstein), scientific concepts have meanings that cannot be reduced to immediate experience. For example, the observational term *mass* has a different meaning in Newton's physics than in Einstein's theory of special relativity. Whereas in previous physical theories, mass was viewed as constant, in the theory of special relativity, mass and energy cannot be viewed or measured as distinct entities. As long as theories partially determine the meaning of observational terms, two investigators attached to two different theories will mean different things even though they might be applying the same observational terms. If theory through which facts are interpreted matters as thoroughly as postulated here, then the formerly upheld empiricist theory–observation dichotomy must be abandoned.

Second, the complementary argument that has further undermined the distinction between logical analysis and experience is the thesis of the *underdetermination of theory by data*. While according to the theory-ladenness thesis, science does not have access to pure *facts* not affected by theories, the theory–observation relation can also be considered from the theory point of view. Considering again the aforementioned example, it could be asked whether the Ptolemaic or the Copernican *theory* should be preferred, although a widely held view in Copernicus's time was that the two rivals did not actually differ in their predictions of the available astronomical data

(although they differed strikingly with respect to the unobservable). In sum, a particular theory is underdetermined by observational evidence. The difficulty has been fueled even further by a complementary argument offered in the 1950s by Willard V. O. Quine, also known as the *Duhem–Quine thesis*. Quine made the holistic assumption that theories can only be tested against evidence as a whole. Experience cannot confirm or falsify individual beliefs but only the coherent set of beliefs that had been fit together to form a theoretical whole. That is, on the one hand, hypotheses cannot be tested individually; on the other hand, any aspect of a theory can be retained by adjusting auxiliary hypotheses elsewhere.

Both of these arguments supported the outstanding success of Kuhn's landmark book—and vice versa. Kuhn's book, first published in 1962, changed the course of philosophy of science in the 20th century, including its understanding of scientific change and, more specifically, of theory change. Before Kuhn, science was understood to be a linear, cumulative unveiling of reality; theory change was not a point of discussion. According to the Google Books Ngram Viewer, *change*—whether scientific change or theory change—was not an issue before the 1960s. Before Kuhn intervened, the further development of a theory was understood as a cumulative growth of knowledge by either accumulation of observational evidence or error elimination, which, according to Popper, supports theoretical progress (since every succeeding theory contains the positive results of the earlier theories). Kuhn changed everything. Since Kuhn, theory change no longer means growth. Moreover, it no longer implies a rational process. Since the 1960s, theory change may involve change in the meaning of the terms used in two succeeding theories; it may therefore represent a radical break. Kuhn's immensely influential book introduced three key concepts: *paradigm*, *scientific revolution*, and *incommensurability*.

First, it is neither observational statements nor isolated hypotheses that matter first in science, rather it is *paradigms*. A paradigm, later also called a *disciplinary matrix* by Kuhn, is more than just a theory. In accordance with the holistic viewpoint outlined above, a paradigm includes a set of background assumptions. It is a deeply anchored general framework that serves several functions at

once. It defines a problem field, it offers a source of methods, and it contains the standards of solution, which are endorsed by all scholars working in the relevant scientific domain. It is most definitely not easy to change. Where Popper saw refutations when theories faced difficulties, Kuhn sees anomalies against which paradigms are immune. That is, where the Popperian scientist has to falsify her hypothesis, the Kuhnian scholar would never give up the paradigm on which all research in her field is based. Consequently, theory change along this line would no longer guarantee scientific progress. The reason is that, according to Kuhn, there are further sources beyond empirical observations and tests that contribute to establishing and keeping a paradigm at work.

Second, once a paradigm does actually change, the scientists concerned will indeed be working in a different world. This happens in *scientific revolutions*. In long periods of *normal science*, the daily work of the scientist could also be described in terms of the above-mentioned philosophies of science. Scientists put the results of their studies together to form a gradually growing body of knowledge. All of them work under the same paradigm. Normal science has to be considered as a conservative period in the history of science. Scientists know and share the rules of the *game*. They simply but ably apply these rules to new phenomena. Contrary to the popular view, scientific research in normal periods of science does not really *discover* anything new, at least not a new view on reality. In actual fact, all scientists share the same view of reality. This changes in revolutionary periods. In *scientific revolutions* such as the 16th-century Copernican revolution in astronomy, the 19th-century Darwinian revolution in biology, and the 20th-century Einsteinian revolution in physics, confidence in the existing paradigm breaks down. A sense of crisis develops in the scientific community. Anomalies that cannot be accommodated in given theories are usually ignored. In revolutionary periods, however, once a growing number of anomalies have accumulated, more and more scientists become open to accepting a new paradigm. In contrast to the gradual growth of knowledge during the period of normal science, a scientific revolution involves a radical shift. According to Kuhn, Galileo, for example, lived in a different world from Aristotle.

Third, the radical-shift thesis is implied in Kuhn's thesis of *incommensurability*. If experience depends on theory, the problem arises that two scientists who hold different theories will mean different things even if they use the same terms to describe their observations. In Ptolemaic astronomy, *planet* referred to the Sun and the Moon but not to Earth. In the Copernican worldview, these meanings have changed. The sun has moved to the center of the solar system, and the Earth and all other planets are thought to revolve around it. If two competing theories are incommensurable in this sense, they are even incomparable, as both standards of comparison, including meanings of concepts, are dependent on the two different paradigms to which they belong. In summary, if theory change is understood as a Kuhnian radical shift, it produces incommensurable conceptual languages and different ontological worlds. Theory change can then no longer be considered a rational enterprise.

Theory Change as Practice

Whereas earlier philosophy of science did not study the *context of discovery*, Kuhn's holistic-historical understanding of theory made philosophers aware of the role of extrascientific factors in theory change. By no longer focusing on rationality in logical extensions and the relation between terms and empirical phenomena, Kuhn's approach invited the study of factors such as the interests of involved scientists, governments, funding agencies, or the influence of technology or gender. Since the 1970s, this kind of research has been carried out extensively by scholars of the sociology of scientific knowledge (SSK). For SSK, science is a social activity; it is practice. Theory change then is no longer regarded as a rational process but as a social enterprise.

While both SSK and Kuhn's view can be understood as the antithesis to the previously dominant logical analysis of scientific knowledge, Kuhn also opened doors to other approaches that take a third path. The study of both *experimental* and *cognitive* practices is of major importance in this regard. Both share an interest in actual scientific activity. Instead of simply comparing two completed conceptual structures, they focus on the *process* of theory change.

First, Ian Hacking's *Representing and Intervening* claims that experiments have a life of their own that is independent of the representation of their results. When scientists use microscopes, they are not applying a theory; they are not just *looking*, they are *doing*, they are manipulating things. Even if different microscopes are used, often the same patterns are found. In this respect, theories are preceded by stable practices. Hacking's view thus makes an important point against the *incommensurability* thesis. Whereas a Kuhnian researcher focuses on that which varies (and then claims that this involves two incompatible worldviews), Hacking's practice-oriented account of theory change considers that which does not vary. In this latter perspective, there is something that is preserved even across theory change that comes to light in experiments. Consequently, Hacking holds a *realist* view of the process of science according to which theory change is not to be regarded as irrational, as it would appear in the light of Kuhn's relativism. While Kuhn denied the existence of a third, commonly shared framework that would be needed to enable the comparison of two succeeding theories, the successful manipulation of things in experimental practices shows that there must be something in reality that corresponds to the theories presupposed in the analysis.

Second, the study of the *cognitive* processes offers a further approach that does not limit itself to the comparison of end products in the process of theory change. Instead, by studying epistemic practices that scientists apply in problem-solving processes, such as analogies, visual models, and thought-experiments, the cognitive approach to science shows how piecemeal transformations of theoretical frames can result in revolutionary changes. For example, Lindley Darden has suggested focusing on the reasoning strategies that could have produced the theoretical modifications of Mendelian genetics between 1900 and 1926. One of the strategies for changing theories that she found is the strategy of *delineate and alter*. It involves the analysis of a component into several parts and then a change to only some of those parts. Another approach that reestablishes reason at the core of theory change has been offered by Paul Thagard, who makes a plea for a *cognitive*

science of science. Thagard proposes to analyze the conceptual system that makes a theory by focusing particularly on kind-hierarchies and part-whole relations in the organization of concepts and then considering which computational mechanism could have produced the components of the conceptual system. His analyses have shown that explanatory coherence is the core mechanism of theory adoption in conceptual change.

While the cognitive approach to theory change moves the focus to a fine-grained analysis of conceptual developments, it still assumes that scientific concepts are embedded in theories that are revisable over time. It thus shares the basic assumption of other forms of historical analysis against the synchronic investigation of the end products of scientific change that there are other rules at work (and to be explored) in the process of theory change, beyond the reference to observational evidence (and its rational reconstruction).

THEORY CONSTRUCTION

Theory construction is a process through which propositions are developed, tested, scrutinized, and revised to explain observations for which no reliable previous explanation exists or for which existing explanations are flawed or incomplete. Several steps are involved in theory construction across all fields of study that enable new propositions to arise while ensuring that those propositions are accurate across a wide range of contexts. In the following sections, each step will be described and discussed in turn.

Theory Origination

Theory construction begins with an observation for which the theorist has no verifiable explanation but does have concepts or constructs that enable recognition of the phenomenon and the generation of a question or prediction about what is observed. Concepts—for example, *shirt* and *jacket*—are concrete ways of labeling phenomena, whereas constructs, such as *style*, are more abstract applications of concepts. *Thought trials*, as Karl Wieck (1989) describes them, are means through which theorists use concepts and constructs to construct questions about observations and consider possible solutions.

Concepts and constructs, in turn, are informed by paradigms that shape theorists' ontological perspectives. Paradigms are general ways of viewing reality that frame how theorists make observations, devise questions, and generate meaning from findings. For example, to some degree, East Asian health sciences operate within a somewhat different paradigm than European or American health sciences, as a result of historical forces having shaped the ways that illness has been conceived and medicine practiced in different regions.

Paradigms fuel theory construction by suggesting what is important to think about, to know, and to investigate. Also, paradigms guide theory construction by suggesting what relationships should exist and what the observable effects of those relationships are likely to be. At the same

time, paradigms can also limit theory construction by conditioning what is perceived, what is thought worthy of exploration, and what sorts of questions are asked.

In the process of theory development, originating paradigms might be found to be faulty if expected relationships and effects found by researchers are absent or different from what is expected within the paradigm. Entire paradigms can be rejected and replaced because they can no longer generate theories that reliably explain observations. Thus, what Thomas Kuhn described as *scientific revolutions* can be the result of theory generation initially inspired by the very paradigms that are subsequently discarded. A classic example is the Copernican Revolution of the 16th and 17th centuries, which replaced the Ptolemaic paradigm of the 2nd century C.E. with a new view of the universe wherein the Earth revolves around the sun rather than vice versa. This shift in paradigmatic thinking made old theories obsolete but opened the way for new ways to explain the universe.

Forms of Reasoning

Theory generation can be either a *deductive* (sometimes called *top down*) reasoning process or generated *inductively* (*bottom up*). When constructing theories deductively, theorists begin with a principle that establishes a horizon of possibilities within the respective paradigm. That principle is then applied to specific observations to refine a singular explanation that will hold true across a wide range of instances. Findings derived from deductive approaches either support the initial proposal or prove the proposal to be false. Theorists must keep an open mind, therefore, to the possibility that new observations might contradict established principles and thus challenge the established paradigm.

Theories generated inductively begin with specific observations in which theorists look for patterns among phenomena of interest. Established theories can be used to explain the patterns, or new theories could be devised where no previous explanations suffice.

A third possibility, less discussed in literature on theory construction, is *abduction*. In this case, unexpected results lead to insights that might not have been conceivable via inductive or deductive approaches. Abductive reasoning relies upon inferences made about causes of unexpected outcomes.

Division of reasoning into three categories for heuristic purposes is, however, somewhat misleading because induction, deduction, or abduction are not entirely separable strategies in theory construction. *Grounded theory*, as proposed by Glaser and Strauss, for example, combines induction and deduction via *the constant comparative method*. Using this method, the researcher moves from observations of specific instances to tentative explanations for those patterns and then back to specific instances to test the tentative explanations. Similarly, abduction requires at least some degree of reasoning based upon known principles to explain unexpected findings which then leads to further testable hypotheses.

Furthermore, as Weick points out, the step-by-step approach of theory building described thus far is an idealized, rational, linear model. In reality, the process is often interrupted and redirected by intuition, emotional response, and unplanned circumstances, inspiring insight, which in turn accelerates, slows, or redirects the theorist's progress.

Analogies are often important elements in the theory construction process, as Brian Haig has observed. Analogies permit inferential leaps of logic from the known to the unknown via comparison of phenomena that are presumably alike in fundamental ways. For example, gatekeeping theory in the field of mass communication research asserts that individuals, policies, and values within news organizations permit some stories to be published (make it through the gate), while other potential stories are not published because of gate closure.

Causation is an important, albeit somewhat controversial, element in theory construction. Theories are developed to explain if, why, and how changes in one concept—the independent variable—affect other, dependent, variables. Within controlled settings, researchers test causation by manipulating independent variables to test the accuracy of relationships expected within the operative paradigm. Beyond controlled settings, researchers can also test

relationships by examining how variables relate to one another in natural settings.

There is some debate as to whether causal relationships are an advisable form of relationship to theorize about, given the unobservable nature of causation. Instead, some scholars such as David Whetten assert that it is more prudent to describe and predict relationships that are either categorical (demonstrating an association between A and B) or sequential (ordered in time so that B is followed by A).

Hypotheses and Research Questions

Hypotheses and/or research questions are developed to predict, inquire about, or at least contextualize specific relationships among variables relevant to the overall theory. Hypotheses are specifically used to test theoretical assumptions by predicting the relationships and effects generated among selected concepts and constructs within the domain of the theory. Specific instances of more general constructs are examined to test whether expected relationships and effects are valid across multiple conditions. For example, if a theory suggests that an increase in playing violent video games leads to a decrease in hostile feelings toward others, then a resulting hypothesis might suggest that an increase in hours male undergraduates spend playing *Tour of Duty* would lead to an increase in those same students' hostility toward female undergraduates.

A research question, in contrast, is not designed to test a theory, but rather to inform inquiry about specific phenomena. Using the same example, a research question might ask about the nature of violence in video games, thus leading to a classification and quantification of types of violence present in the game. In short, research questions can function to explore relationships among variables, whereas hypotheses test for expected relationships.

Variables, in turn, can be quantifiable and thus measurable, or they can be more qualitative and conceptual. For example, the average number of hours students study per day can be measured by tallying study hours among a sample of students over a number of days and then dividing the total hours by number of days and number of students in the sample. In contrast, attitudes and beliefs

about studying are less easy to quantify but may be gauged in relative terms by the ways studying is discussed in personal narratives among students in the sample.

Once hypotheses and/or research questions are devised, a methodology is determined for collecting and analyzing data. If human subjects are involved, studies' purpose and method of data collection must be approved by institutional review board of sponsoring organizations. Data are then collected and analyzed following the planned methodological steps.

Professional Scrutiny

To build a credible theory, data observed, study findings, and the reasoning process used to interpret the data are written in a format with the intent of publication in a scholarly research journal or book. Research reports are typically organized in a patterned way with the importance of the topic stressed first, followed by a literature review summarizing what other scholars have already found regarding the topic and perhaps how other theories have been used to explain the topic. Having thus set up the intellectual context of the study, the hypotheses and/or research questions driving the study are described as is the method used to collect and eventually analyze the data. Findings are then summarized and explained in relation to the generating theory. Limitations and weaknesses of the study conclude most written reports along with new questions raised by the study.

Prior to publication, research reports are usually presented to scholars and practitioners at professional conferences for review and critique. Most often, to be eligible for presentation, scholarship must pass through a *blind* peer review process wherein two to four anonymous researchers—representing a range of expertise from graduate students through tenured faculty members—are asked to read and rate submissions. Conferences at the national level might accept as few as one in three submissions based on a number of factors including application of theory, strength of the research methods, and validity of conclusions reached. In well-organized conferences, anonymous written feedback from reviewers can be helpful in pointing out areas in need of improvement and to

reveal hidden assumptions overlooked by the researchers. For those papers that are accepted for presentation, further feedback can be provided verbally by conference attendees present when the paper is presented.

Research need not go through the conference step but might instead move directly into the publication stage of the theory-building process, which, again, opens the work to professional scrutiny. Publication widens the circle of scholars and practitioners available to critique and perhaps use the written work to further extend theoretical principles put forward. Publication requires further peer review to ensure the validity of the methodology and theoretical principles presented in the work and may take the form of books, book chapters, or journal articles.

Although it violates the spirit of objective scientific research, status of the publication plays a strong part in whether a proposed new theory gains traction in the academic world. *Top* journals and book publishers have greater name recognition and respect among scholars and the public press than lesser known publishers and thus command more attention. This is particularly important regarding the public press which, as an industry, has much more leverage to promote or discredit ideas in the global market than do academic presses.

As hypotheses and research questions garner attention and develop growing bodies of predictive and explanatory knowledge within the community of scholars and practitioners, the cases to which tentative theories can be applied widens. At the same time, alternative explanations also might be developed to test the validity and scope of initial hypotheses.

Once proposed, theories are continually tested, not to prove them true as is the popular conception but, rather, to prove them false. Through their assertions regarding predictable, observable cause-effect relationships, theories suggest where researchers look to test the theory. By trying to find conditions and circumstances in which theoretical predictions are not present or accurate, researchers can suggest theoretical limitations and perhaps rejection of theories in part or in whole. On the other hand, research that fails to disprove theoretical assumptions or that supports theoretical predictions in previously unexplored

circumstances, in turn, strengthens the theory by demonstrating its validity and reliability.

Besides the option of testing theories empirically, theories can also be evaluated at face value by examining a number of constitutional factors. Such evaluation determines whether new theories are accepted, tested, used, and further developed.

A number of criteria are used to judge the strength and value of theories. Theories should be clear in their description of what concepts are involved and how they are defined, the extent of phenomena covered, their explanatory or predictive purpose, and their succinctness. Theories also should be concisely worded, consistent, coherent, and avoid unnecessary conceptual and verbal complexities. They should make significant contributions to their respective fields—and ideally, to other fields of study as well. Theories should explicate their own contextual limits while leaving latitude for further application and expansion. Finally, as Whetten notes, theories that are both comprehensive and useful in their breadth and depth of application will have more chance of being accepted than those with narrow ranges of application.

Over time, what had once been a tentative assertion develops enough scrutiny, support, validation, and potential explanatory power to be considered a widely recognized theory. This process could take years and might never reach this stage if the theory is disproven along the way. Conversely, some theories accrue lasting power to the extent that they are repetitively supported in a wide range of times and places.

Popular conception is that given enough verification and scrutiny, a theory becomes a law or a fact. This line of reasoning is erroneous, owing to a misunderstanding of what a theory is. Whereas a theory is an explanation of why and how things occur, facts are verifiable occurrences. Therefore, it is safe to say that the function of theories is to explain and predict facts. As long as the explanation holds true for verifiable facts, the theory is considered valid.

This is not to say, however, that facts cannot be disproven. It was once considered a fact that a specialist could determine personality traits from the shape of a person's skull. This supposed fact was informed by the theory of phrenology, but both theory and *fact* have long since been

discredited. On the other hand, facts can remain valid even when theories devised to explain them have been disproven, thus opening the way for new theory generation.

Similarly, theories do not evolve into laws over time, contrary to popular perception. Laws describe relationships and effects, whereas theories explain how and why those relationships occur. Whereas laws reliably predict *what* will happen, theories explain *why* they happen. Once established, laws are far less malleable than are theories, which are continually refined to encompass a wider range of facts. Therefore, it would be more appropriate to say that theories can expand to include laws, but they do not morph into laws.

Under some circumstances, it is possible for researchers to become protective of theories, preventing scrutiny necessary for the theory's vitality and growth. As Robert Wyer points out, researchers can be bound by an over-dedication to the theory with which they have become accustomed and might become professionally associated with. In such cases, well-meaning theorists can become hampered by the conceptual boundaries defining the theory in question. The danger in such cases is that theories can become dogmatic. Rather than looking for weaknesses in theory, researchers can potentially become so committed to a theory that their research becomes a repetitive series of tropes to illustrate and support the theory, with little opportunity for theoretical expansion or for critique.

Salience of Theory Construction

Overt attention to theory construction waxes and wanes through time and across disciplines. Evident interest in the theory construction process is often a reflection of external sociopolitical events, on one hand, and ongoing debates within academe surrounding the need for theory, on the other. For example, continued social awareness of growing economic disparities could lead to renewed interest in theories inspired by Marxist philosophy as ways to explain those disparities. Also, as fields grow in terms of professional interest and research, the need for theory to explain bases of the field may arise in the effort to move the field beyond the initial stages of practical application of a limited set of concepts.

Interest in new theory construction can wax and wane in conjunction with cross-paradigmatic conflict. Academic friction between positivist and constructivist paradigms is a case in point wherein the nature and purposes of theory are continually debated. Indeed, this particular conflict has, since the early 1980s, raised fundamental questions about how theories are constructed, asking whether theories can be truly rational and separate from negotiation and compromise conditioned by historical circumstances.

Whether or not it is a predominant topic of research interest in itself or a practical means of explaining reality, theory construction is a crucial factor in the ways that we understand and engage with observable phenomena within all fields of the humanities and sciences.

THEORY STRUCTURE

Across the sciences, practitioners use theory to explain and predict a wide range of phenomena. Some type of theory is found in virtually all scholarly disciplines and areas of inquiry—in the physical, life, and natural sciences; the social sciences; and in the arts and humanities. As a result, theory—and what constitutes a good one—means different things to different people. For example, for those in the physical sciences, theories that address interacting or colliding elements (e.g., particles) seek to explain a change in state of one or more of the elements. In contrast, theories in the social sciences are often more abstract than physical theories; they tend to lack a mechanism that is thought to impel the elements, specified as variables, to change in magnitude on a single attribute. For example, an individual's (i.e., an element's) contact with dissimilar others (an attribute) is thought to increase the individual's tolerance of dissimilar others (another attribute). The causal relationship is present, but the mechanism is not.

Such differences in theoretical orientation lends to theories being classified as either scientific or nonscientific, with those theories that logically predict observable patterns of phenomena (scientific theories) in one camp standing in

distinction from those with a more ideological and/or informal nature (nonscientific theories). For the purposes of developing objective knowledge about the way the world works, scientific theory is the most preferred across disciplines. Scientific theories feature a structure that one can order and delimit. The most prevalent formal classifications that represent structures of scientific theory are *theories as axioms* and *theories as models*, which are closely coupled with the *syntactic view* and the *semantic view* of theory. The following sections discuss such distinctions, summarizing how theory is structured across the sciences.

Theories as Axioms

Throughout the history of science, axiomatic theory—often referred to as *deductive theory*—has been the accepted framework/structure of scientific inquiry. Philosophers of science have termed this mode of theory the *received view*, due to its widespread use across disciplines until the 1970s. Central to axiomatic/deductive theory is that all predictions and propositions stem from axioms, otherwise known as *postulates*; it is from such statements that theories originate. Axioms refer to ideas or knowledge claims we take for granted—ideas that are assumed to be true in order to understand that which follows from them. Axioms contain abstract, interrelated concepts—semantic devices that denote phenomena—that state the essence or process of something in the world. Further, axioms are generally not provable (which is why they are axioms/postulates rather than facts or laws). In physics, an axiomatic statement might be that “space is three-dimensional.” In biology, an axiom might take the form of “cells are the basic unit of life.” A general axiom in science is that the “universe is rational,” or put differently, x is not equal to $-x$.

Axioms exhibit a hallmark of deductive theory—a syntactical structure. Theories of this nature are illustrated by sentences consisting of both a logical and extralogical vocabulary. Logical symbols in theory have their foundation in mathematics and include connectives such as *and*, punctuation symbols such as brackets ([]), variables (such as x , y , and z), and symbols representing varying states

of equality ($=$, $\neq$). Those who are unversed in formal logic are likely more familiar with theories stated using extralogical vocabulary. Extralogical vocabulary consists of a theory’s descriptive terms, or concepts, which refer to observable or unobservable phenomena. Concepts rely on their definitions for understanding in the sense that one is only given meaning when defined. For example, one definition of a *role* is a sequence of gestures marking a course of action. This allows investigators of all types (students, researchers, and philosophers of science) to comprehend the phenomenon denoted by the concept. Ideally, the concept will take on a uniform meaning such that all investigators are in agreement when dealing with the phenomenon.

In the structure of theory, concepts are distinguished by whether they simply label a phenomenon or refer to one that pertain to differences in magnitude. Concepts of the first kind include the atom and electron; concepts of the second kind include atomic mass and electrical charge. Concepts that simply label phenomena are abstract and do not refer to concrete times and locations—they can be generalized. In contrast, concepts that relate to magnitude may vary in terms of size, weight, speed, and force. When we define concepts by their variable properties we have, *ipso facto*, translated them into variables. Thus, scientific theories often seek to demonstrate how variation in one phenomenon explains variation in another.

According to the received view, concepts are connected to one another via interrelated statements. When employed correctly, the statements follow a process of deduction, beginning with axioms/postulates and then deriving propositions from them. Until recently, this was the theoretical structure most often used in the sciences and the one most advocated in philosophy. At its fundamental level, a proposition should specify the connection between two or more variables. For example, the proposition “the stronger the degree of social integration in a society, the lower the society’s rate of suicide” contains two variables (*degree of social integration* and *suicide rate*). The propositional statement not only connects these two variables but also asserts an indirect and inverse relationship. Propositions can also differ in their level of abstraction, which is demonstrated

frequently in the social sciences. As such, a series of propositions may seek to explain all economic crises in general while another propositional system may link empirical facts concerning the Great Depression. This distinction leads to a common question about theory: Are empirical formats, which consist of generalizations that do not stem from axioms, really theoretical? One supported empirical generalization is that democratic nations, rarely, if ever, go to war with one another. This proposition, from the discipline of political science, is not very abstract, and deals with the observable concepts *democracy* and *war*. Furthermore, the concepts do not characterize a whole class of phenomena. If this were the case, *democracy* would be replaced by *political systems* and *war* with *conflict*. Ideally, relationships in a theoretical system should be deduced from a highly abstract assumption (axiom), but this is not the case. Instead, linked as it is to empirical contexts, it is simply a generalization that needs a theory to explain it. Even so, scholars in many areas would not hesitate to declare such statements as a *theory*.

To be sure, a rigid, parsimonious, and robust axiomatic/deductive theory is difficult to achieve. In fact, among philosophers of science, there is little consensus on which *theories* precisely adhere to the principles of pure, axiomatic theory. Nevertheless, when structured appropriately, there is arguably no theoretical form more powerful. Given the interrelatedness of axioms and propositions, empirical support for one or more of the propositions simultaneously signals support for the axioms from which they were derived. This is more plausible in the physical and biological sciences, where concepts are stated with more precision and exogenous factors are more controlled for than in the social sciences. Even so, the structure has fallen out of favor from scholars of all stripes during the last few decades as alternative, (perhaps) more practical approaches have emerged.

Theories as Models

The structure of what is accepted as theory changed from the *theories as axioms* perspective to the *theories as models* perspective roughly a half century ago. This shift occurred for various

reasons including the notion that treating theories as models allows for more flexibility in theory construction and applicability to a wider array of phenomena. An irony of this shift is that while many abandoned the received view for the *improved* models view, there is no consensus on what actually constitutes a *model*, or how models operate as theory. As summarized by Carl Craver, models are structures that support the validity of a theory, whereby (1) theories specify or define abstract, idealized systems; (2) models are the structures that satisfy these specifications or definitions; and (3) models are similar to some phenomenon (or system) found in the real world. Models thus are useful tools for understanding and predicting real-world events/processes, assuming a model indeed is an accurate proxy of that which it represents. In this view, models can be representations or simulations (e.g., a scaled abstraction of something, such as an atlas, map, or globe), abstract logical statements (e.g., mathematical expressions that stand for an empirical process), analogues (e.g., using Easter Island's societal collapse due to overpopulation as a comparative model for understanding potential outcomes of contemporary societies with population pressures), or experiments that serve as proxies for understanding real-world phenomena (e.g., the experiments by psychologist Stanley Milgram on obedience to authority).

Jonathan Turner conceives models as constructive tools that represent a range of activities; models involve concepts and their representations as a picture—an image, so to speak, of the crucial elements of a system or process. In this perspective, models are analytic devices that relate concepts to one another—they are diagrammatic representations of phenomena or events. Models as diagrammatic representations include (1) concepts that denote and isolate specific elements or features in the world, (2) the purposive arrangement of these concepts into a systematic imaginary or visual space so that they signify their interconnectedness, and (3) some symbolic marker that reveals the meaning of such interconnections among the elements in the model. Following this, models take two general forms: one *analytical* and one *causal*. Analytic models are more abstract, addressing generic properties of the universe. Analytic models depict

a complex set of connections among concepts/variables in an explanatory system. Analytic models are appropriate for connecting concepts described in an axiomatic or formal theory. Causal models are less abstract and more empirical, often addressing the individual or particular properties of empirical cases. Causal models are appropriate for understanding how measured concepts (variables) relate to each other and how such concepts account for variation in a specific outcome. Causal models often—but not always—represent the direct causal connections among elements in a system. For example, a causal model might represent the effect of population size in a society on the differentiation in that society's division of labor as a linear (or curvilinear) function. By constructing a model based on these criteria, one can identify the causal patterns that exist among a wide array of concepts/variables that exist in a system. Models thus provide scientists with a relatively simple, elegant mechanism by which to understand process, causality, and change in phenomena across scientific disciplines.

Significant differences between the theories-as-axioms and theories-as-models view are often difficult to identify. The most obvious difference is that the theories-as-models perspective moves away from propositional deductive statements and toward abstract representations or schemas that depict some phenomena. Other differences regard the fact that the theories-as-axioms view is defined by *syntax*; because of this axiomatic theory is thus sometimes referred to as the *statement view*. The theories-as-models view is more defined by *semantics*; because of this it is sometimes called the *nonstatement view* (see Craver's useful discussion of these distinctions).

Debate over a theory's syntactical and semantic components is crucial given that the failings of either can weaken all results stemming from a theory's research program. The debate, which has continued since the 1960s, concerns whether either view can adequately describe scientific theories. Proponents of the syntactic view stress its formal nature and connections to experiments and observations. Sentences are written in *higher order logic*, with one set of terms reserved for observational language. Critics of this approach

feel that formalization in such logic is cumbersome and that theorists should rather describe observational data as occurring in a physical space composed of varying inputs and outputs. This alternative is articulated in the semantic view, which relies more on the adaptability of mathematics than the rigidity of logic. To its critics, the semantic view is too vague when one must interpret what precisely a theory is explaining (see James Mattingly's critique of the semantic view for an elaboration on this theme). Further problems borne out of this debate involve how new theories come about from seemingly problematic older ones. As a result, hybrid approaches including tenets of both the syntactic and semantic views have been proposed.

Additional Dimensions of Theory Structure

In addition to the axiomatic and models perspectives described above, the structure (or components) of a theory can be classified along other dimensions. One such dimension regards whether a theory is *formal* or *informal*. Formal theories often have deductive propositions or interrelated statements that follow from one another and often involve logical or mathematical expressions. An example of a formal theory is Guillermina Jasso's theory of comparison processes, which uses formal expressions to represent how individuals compare resources to one another: the axiom of comparison states that there exists a Class Z of human individual phenomena that are produced by the comparison of an actual holding (A) of a good (or a bad) to a comparison holding (C) of that good (or a bad), such that Z is an increasing (or decreasing) function of A and a decreasing (or increasing) function of C :

$$Z^G = Z^G(A, C) \quad \partial Z^G / \partial A > 0 \quad \partial Z^G / \partial C < 0$$

$$Z^B = Z^B(A, C) \quad \partial Z^B / \partial A < 0 \quad \partial Z^B / \partial C > 0$$

By contrast, informal theories are less rigid conceptual frameworks that describe some phenomenon or process, often using narratives to explain the nature of something. Standpoint theory, a controversial theoretical framework that has

emerged in sociology, provides an example of an informal theory.

Another dimension of theory structure regards the *scope conditions* of a theory or the range of phenomena a theory purports to describe or explain. For example, in social psychology, expectation states theory (EST) is a predictive theory of behavior that examines the influence of status on individuals' performance in groups. EST has two scope conditions in which the theory is predictive: in task orientations (when group members are motivated to solve a problem) and in collective orientations (when group members consider it legitimate and necessary to consider each other's contributions). Scope conditions are important in theories as they delimit the explanatory range of a predicted outcome.

Another dimension of theory structure regards *level of analysis*. Theories—particularly in the social sciences but not unique to them—can be conceived as explaining micro-, meso-, or macro-level phenomena, depending on the area of inquiry. For example, theories addressing processes at the atomic level might be considered microlevel theories (such as Dalton's atomic theory); theories examining the nature of the larger universe would be considered macrolevel theories (such as Doroshkevich, Sunyaev, and Zel'dovich's theory of galaxy formation from cluster pancakes). There is no ultimate bifurcation point or ultimate consensus on what would define a theory at any level of analysis, and such distinctions are usually only relevant for placing a theory within an understood domain or common area of inquiry. Levels of analysis can be important though as some theories predict outcomes at one level of analysis differently than for others (e.g., processes at the quantum [micro] level are conceived to operate uniquely as compared to processes at other levels of analysis).

In general, theories consist of components—differing structures—that help define, explain, and predict phenomena. Although what constitutes a theory's structure may differ in form and the level of abstraction from theory to theory, all theories—regardless of structural form and complexity—are aimed at assisting scientists and scholars in better understanding the world.

THEORIES, SEMANTIC CONCEPTION OF

The semantic conception of theories holds that a scientific theory can be identified with a collection of models. This view was originally put forward by Patrick Suppes in “A Comparison of the Meaning and Uses of Models in Mathematics and the Empirical Sciences” with the aim of repudiating the *received view* of theories then popular in logical positivism. This entry discusses the foundations and development of the semantic conception of theories, starting with the view that theories should be viewed in terms of models. We will also look at the advantages of a model-based approach, and how models could provide a better pathway to discovering the laws of nature.

The Classical View of Theories

In the early days of symbolic logic, theories tended to be *axiomatized*—for example, arithmetic, as illustrated by Peano's axioms, and the geometry of Euclid, as formalized by David Hilbert (1862–1943).

These mathematical theories involve a kind of axiomatization with some of the axioms thought of as definitions and others as laws. This classical view is associated with the *H-D view* of confirmation as used by Carl Gustav Hempel (1905–1997), the idea being that you confirm a theory by using it to make predictions about an observable phenomenon, then check to see whether the predictions are correct. For Hempel, predictions are structurally identical with explanations: The premises need to include at least one law and some initial conditions, then a statement is deduced about something observable. Put simply, the classical view looks at theories as collections of sentences. So the classical logical positivist view construes a theory as a set of sentences in an axiomatized system of first-order logic.

Foundation of the Semantic Conception of Theories

Bas van Fraassen (b. 1941), a key founder of the semantic conception of theories, has strongly criticized the syntactic view for focusing attention on technical questions which are irrelevant from a philosophical point of view. The discussions of axiomatizability that take place in restricted vocabularies and use *theoretical terms* lead to unnecessary self-generated problems. Rather than lend itself to an axiomatic approach, science, according to van Fraassen, should be seen as defining mathematical models directly, with the focus on the connections between theoretical terms and language that are more readily understood.

During the 1960s, philosophers of science began to explore different approaches to scientific theories. One prominent approach was the semantic conception, according to which theories are viewed as collections of models together with hypotheses describing how these models relate to different areas of nature. There were numerous

views about how to characterize these models, and whether they should be looked at as abstract mathematical structures, open to precise formal specification, or whether they should be taken to be more concrete, like the molecular models built by chemists.

The semantic view repudiates the syntactic view of theories, upheld by the logical positivists and empiricists. The *syntactic conception* of a theory affiliates it with a body of theorems, in a language particularly selected for that theory. The alternative semantic conception sees the theory as being identified with a class of structures as its models in language which is neither basic nor unique—that is, the same class of structures could be described in quite different ways, within its own limits, thus ensuring the models take center stage. Hempel and Rudolf Carnap (1891–1970) are two main proponents of the first, syntactic view of theories.

The semantic view holds that theories as models or sets of models. Some semantic views suggest that theories should be identified with a Tarskian class of set-theoretic models, while others propose that models should be set out in mathematical language that relates to the field in which the theory belongs as a member. Whereas semantic views differ, they all take as central to their notion the model as the unit of scientific theorizing. (Polish logician Alfred Tarski [1901–1983] undertook work that would lead to rigorous definitions for notions useful in science methodology. He published a paper that would give his analysis of the notion of a true sentence for a given formal language. For him a language is fully interpreted if all its sentences have meanings that make them true or false.)

A *model* is a system of semantic rules that interpret an abstract calculus, thereby applying scrutiny to the semantics of a specific language. For example, in the kinetic theory of gases, if we take the mathematics used in the theory and reinterpret the terms of calculus so that they refer to billiard balls, the billiard balls are a model of the kinetic theory of gases, a semantic model. Logical positivists, such as Hempel and Carnap, believed that such models are superfluous to scientific study, holding that they are at most only of pedagogical, psychological, or aesthetic use. Proponents of the

semantic view of concepts, such as Franz von Suppé (1819–1895), van Fraassen, and Ronald Giere (1938–2020), think the opposite and that we should reject formal calculus and take the view that a theory is a group of models.

Critics of the semantic view believe that theories are not constructed in this way; models are generally independent from theory, rather than being part of them. They are in many ways autonomous agents. This can give them two aspects: *construction* and *functioning*.

Construction of Theoretic Models

When we look at how models are constructed in actual science, we can see that they are derived completely neither from data nor from theory. Theories do not provide the algorithms for constructing a model; the process is not akin to a vending machine—we cannot put problems in and receive a ready-made model. A good example of this is the London model of superconductivity. There is no justification for the model's foremost equation (it cannot be derived from electromagnetic or any other theory). It is motivated purely on the basis of phenomenological pretexts. Basically, the model has been constructed from the *bottom up* rather than from the *top down*, giving it a good deal of independence from theory.

That models are independent also means that they perform functions they could not perform if they were part of, or strongly reliant on, theories.

To recap: According to the semantic view, a theory is a model or set of models.

The model, or models, may be accompanied by theoretical hypotheses that link the model with some real-world phenomenon. A model can be large scale, a map, a diagram, or an analogy. More commonly in science, we have mathematical models: Sets of equations that are thought to capture real-world phenomena in an idealized form.

The Role of Semantic Models in Science

Increasingly in the neurosciences and in psychology, there is a need for computational models or computational architectures, or programs devised

to capture some aspect of the human condition. Semantic models can fill the gaps in theories like classical mechanics and quantum physics, theories that do not represent anything in the material world of (naive) realism. They can provide a concrete representation filled with the details of a specific situation, rather than a theory standing on its own.

Models can achieve results where theories cannot, for example, when theories are too complicated to handle. A simplified model can provide a solution. Quantum chromodynamics, for instance, is a theory that is difficult to use to study the hadron structure of a nucleus, although the theory is fundamental in order to solve the problem. One way around this was to construct a model to describe the various degrees of freedom of the system being considered. The advantage here is in getting actual results rather than silence.

The disadvantage is that it is not at all easy to understand the relationship between theory and models, since the two are in a sense, contradictory. In a more extreme case, we can use a model to help where there are no theories available at all. This is particularly common in the fields of economics and biology, where there are sometimes no overarching theories to call on. In this case, scientists tend to work with *substitute models*.

Relatedly, we can see a theoretical model as a kind of definition. In particular a theoretical model defines a certain kind of system, for example, a classical particle system or, in genetics, a Mendelian system.

Advantages of Using a Semantic View

The benefits of using a semantic conception of theories include the fact that because the theory is based on a model it cannot be false, since it is just a big definition of a *kind* of system. Thus, we do not need to figure out which parts of the theory are definitional and which are empirical, which could be a positive factor. With regard to Newton's second law, $F = ma$, is this an empirical claim or a definition of force? Or is it a partial definition of mass or acceleration? It is not clear.

Viewing a theoretical model as a definition, however, is not to say it does not have empirical

content. Content is included by way of the theoretical hypotheses. The theoretical hypothesis supplies the hypothesis that a real physical system is a system of the type defined by a model. We could put this as saying that a theoretical hypothesis says that some part of the real world is similar to the model.

This brings us to issues of realism. Van Fraassen believes that realism sees theories as literally true. Whether this means exactly or completely true is not apparent, but on this basis it suggests that a model is never either exactly or completely true: The resemblance between model and reality can never be absolutely perfect. But when it comes to some things, we should not interpret realism in such a way as to require it to be strong. It is sometimes claimed that the practice of building models favors anti-realism over realism.

Anti-realists point out, however, that the truth is not the main goal of scientific modeling. Nancy Cartwright puts forward several case studies that illustrate that good models are often false, and that supposedly true theories may not help when it comes to understanding, for instance, the working of a laser. Realists reject the view that the falsity of models makes a realist approach to science impossible, believing that a good model, even if it is not actually true, has a close approximation to truth.

Ronald Laymon argues that a model's predictions become better as we relax the idealization of the world, a view which he purports to support realism. The notion of an approximate truth is, however, too vague for anti-realists. There is no reason to assume that a model can be improved by de-idealizing it even if this were in line with accepted scientific practice, which it is not. Rather than putting effort into repeatedly de-idealizing existing models, they might better be shifting to an entirely new modeling framework once the adjustments become highly involved. A further problem with the concept of de-idealization is that it is not *controlled*. It is not clear how one could de-idealize a model to arrive at the supposedly correct underlying theory.

Laws of Nature

Science aims to discover the laws of nature, and philosophy has been given the challenge of explicating what these laws are. The two dominant accounts are the *best systems* approach and the *universals* approach, and these propose that the laws of nature apply to everything in the world.

This position does not appear to square with a view that imagines models at the center of scientific theorizing. What role can general laws play in science if models represent what is happening in the world, and what is the relationship between models and laws? One response could be that the laws of nature govern processes and entities in a model, rather than those in the world. In this scenario, fundamental laws do not state facts about the world but are true of the entities and processes in the model.

With no real counterpoint to this view given by realists, the challenge remains to understand how and if a realistic understanding of laws and a model-based approach can be reconciled.

Semantic views have many credible features, for example, they provide a way to discuss aspects of science without recourse to a particular language. They also seem to do more justice to scientific fields that resist axiomatization. One good example of this is Charles Darwin's theory of evolution. When the axiomatic approach was in its heyday, philosophers attempted to show how the evolutionary theory could be brought within the confines of orthodox conception of theories.

What happened was that they ended up producing formal theories bordering on triviality and ridiculous questioning about whether the theory of evolution was a tautology. The semantic conception then looked like a far more sensible approach, since it shed useful light on theoretical issues arising in contemporary evolutionary biology. In *The Structure and Confirmation of Evolutionary Theory*, Elizabeth Lloyd argues that the semantic account is more appropriate and powerful.

The semantic conception suits the practice of idealization, an often neglected area of science. Rather than seeing scientists as desiring to give literally correct descriptions of objects in the world, the semantic conception proposes that they instead conceive models accompanied by

claims that particular parts of nature correspond to these models in specific respects and to specific degrees. The debate over scientific models has major repercussions in the world of the philosophy of science. Scientific realism, reductionism, explanation, and the laws of nature were couched in terms of theories because theories alone were believed strong enough to carry the weight of scientific knowledge.

the early 1970s for a variety of reasons. According to the positivists, a scientific theory consists of a deductively closed set of sentences in a vocabulary partitioned into an observational part and a non-observational, or theoretical part. The cognitive significance of the latter required special justification given the rejection of metaphysics as void of content on positivism's preferred account of meaning. According to that account, a statement can be regarded as either true or false only if either (1) it is analytic or contradictory, in which case it has logical significance, or (2) it can be tested directly by observation or experiment, in which case it has empirical significance. Metaphysics, it was claimed, has neither. But one did not want the same verdict for the sentences of scientific theories essentially involving theoretical vocabulary. Two programs resulted. One attempted to provide the theoretical language with indirect or partial empirical significance. The other aimed to show that theoretical vocabulary can be eliminated without detriment to the aim and function of scientific theories. Neither program developed satisfactorily, and the syntactic view was dropped for a variety of reasons.

Formative Influences

The framework out of which the syntactic conception grew was laid by logical positivists of the Vienna Circle during the 1920s and early 1930s, especially with the verifiability theory of meaning. The development of the syntactic view began with the publication of "Testability and Meaning" in two parts in 1936–1937, only after its principal founder, Rudolf Carnap, had emigrated to Chicago.

Logical positivists drew inspiration from two main influences. One was the development of formal logic in the late 19th and early 20th centuries, which considerably aided progress in the foundations of mathematics by using formal languages and the axiomatic method. Mathematical theories so formalized included arithmetic (Giuseppe Peano), Euclidean geometry (David Hilbert), and Cantorian set theory (Ernst Zermelo). Among the fundamental unsolved problems in mathematics, Hilbert included, as the sixth, a mathematical axiomatization of physics.

THEORIES, SYNTACTIC CONCEPTION OF

The syntactic conception of theories, often called the *received view*, originated with logical positivism in the 1930s and began to fall out of favor in

The other driving factor derived from an antipathy to the philosophical idealisms of G. W. F. Hegel and Francis Herbert Bradley and to metaphysics in general. This led to the verificationist account of meaning. The meaning of a statement is the method of its verification: no method, no meaning. An example that impressed Moritz Schlick, the founder of the Vienna Circle, was Albert Einstein's 1905 critique of absolute simultaneity. The claim that Event A is simultaneous with Event B has no meaning in the absence of a means of verification. There is no frame-independent technique. Rather one has, as introduced by Einstein, a frame-relative method by using light signals to synchronizing clocks at rest in the frame. Metaphysical claims are especially wanting. It eventually became clear, however, that the verificationist criterion is too strong. For example, universal claims cannot be conclusively verified since one cannot preclude the discovery of a counterexample. Hence, Carnap replaced the verificationist criterion with the weaker requirement of testability—that is, verifiability or falsifiability, and, in general, confirmation (or disconfirmation) to a degree. Metaphysics remains meaningless under this relaxation.

The Empirical Significance of Theoretical Terms

How, then, do the theoretical terms of science acquire meaning, or empirical significance? No problem arises if a theoretical term is explicitly definable in terms of the observation language. Suppose the term in question is a monadic predicate Px . It is explicitly definable in this way just in case there is an observation language formula $\phi(x)$, in which just the variable x is free, such that the sentence $\forall x(Px \leftrightarrow \phi(x))$ is a consequence of the theory. (Function terms, including individual constants, are handled similarly if certain existence conditions are fulfilled.) Then, if c is a name for an observable entity or else a previously defined theoretical term, the truth of the sentence Pc can be tested by testing whether or not $\phi(c)$.

Unfortunately, few theoretical predicates in actual theories are explicitly definable. To fill this void, Carnap introduced the notion of *reduction sentences*. To simplify, such a pair amounts to

specifying an observable condition sufficient for a theoretical claim ψ and an observable condition sufficient for the negation of ψ . This yields a decision procedure for ψ if it can be guaranteed that one or the other condition holds. But in the absence of both, whether ψ is the case remains undetermined.

Later positivists took a looser attitude, requiring only that there be so-called bridge laws among the axioms connecting theoretical with observation terms just in virtue of essential co-occurrence in the law. Via the bridge laws, the theoretical terms acquire (at least partial) empirical significance by *osmosis* from the observational roots of the theory.

The Eliminability of Theoretical Terms

Alternatively, one can seek to eliminate the theoretical language in its entirety and claim that the theoretical sentences together with bridge laws amount to *inference tickets* between observation sentences. This stance is often referred to as *instrumentalism*.

The Theoretician's Dilemma

But how to eliminate the theoretical language? Explicit definability of all theoretical terms would suffice, but we have seen that this is unrealistic. Another method is to presume that the theory is formulated in first-order logic, so that the set of consequences of the theory is effectively enumerable. The set of all observation sentences is therefore effectively enumerable simply by deleting any sentences containing theoretical terms from the enumeration. Moreover, William Craig showed that any effectively enumerable set of sentences is axiomatizable. Thus, one recovers an axiomatized theory entirely in the observation language, having exactly the same observational consequences as the original theory.

Nonetheless, success here just raises the question of what purpose theoretical terms might serve beyond mere convenience. If none, the theoretician has the dilemma that theoretical terms are in principle dispensable. Even though he had no proof, Carl Gustav Hempel countered that even if a theory provides the same deductive

systematization as its Craigian replacement, it may provide augmented *inductive* systematization. Using Jaakko Hintikka's two-dimensional account of inductive inference, Raimo Tuomela claimed to vindicate the indispensability of theoretic terms for inductive tasks.

Ramsey Eliminability and Empirical Content

So far, we have given the impression that the empirical content of a theory consists in the set of consequences in the observation sublanguage. However, there is a second candidate definable in terms of the models of the theory. Suppose the observational vocabulary consists of terms $O_1, \dots, O_n$ and the theoretical vocabulary terms $T_1, \dots, T_m$. Suppose further that the theory is formulated in first-order logic. A model $\mathfrak{A}$ of the theory has the form $(|\mathfrak{A}|, O_1^{\mathfrak{A}}, \dots, O_n^{\mathfrak{A}}, T_1^{\mathfrak{A}}, \dots, T_m^{\mathfrak{A}})$, where $\mathfrak{A}$ is a non-empty set and each $O_i^{\mathfrak{A}}$ and each $T_j^{\mathfrak{A}}$ are either a relation or an operation on $|\mathfrak{A}|$, depending on whether the term in question is a predicate symbol or a function symbol. For such a model, let $\mathfrak{A}_0$ be the restriction $(|\mathfrak{A}|, O_1^{\mathfrak{A}}, \dots, O_n^{\mathfrak{A}})$ of $\mathfrak{A}$ to the observation language, alternatively called the *reduct* of $\mathfrak{A}$ to the observation language. Must it be the case that $\mathfrak{A}_0$ is a model of the set of consequences of the theory in the observation language? For some theories yes, but for others no. If every reduct of the theory is a model of the set of its observational consequences, then the theoretical language is said to be *Ramsey eliminable*. For a theory whose theoretical language is Ramsey eliminable, it makes no difference if we represent the empirical content of the theory by the set of consequences in the observation language or by the class of reducts of models of the theory. But if the theoretical language is not Ramsey eliminable, then the class of reducts of models of the theory is the preferred representation of the theory's empirical content. For this class represents the possible observable situations permitted by the theory, whereas the set of consequences in the observation language is satisfied in certain circumstances ruled out by the theory.

Thus, if the theoretical languages are typically Ramsey ineliminable, it might point to a positive function for them. Joseph Sneed, in *The Logical Structure of Mathematical Physics* (1971), conjectured that mass and force are not Ramsey eliminable from Newtonian mechanics. Robert Rynasiewicz (1981) disproved the conjecture. Herbert Simon and Guy Groen thought that Ramsey eliminability holds generally for all reasonable theories, where the criterion of reasonableness demands that the theory be finitely and irrevocably testable (FIT). But this requires that every substructure of a model of the theory also be a model or, equivalently, that only universal quantifiers appear in the axioms when cast in prenex normal form. This rules out theories with existential commitments, and so, given the prevalence of these, FITness appears to be an unreasonable requirement.

Partial Structures and Empirical Content

Bifurcating the language is intended to distinguish between those properties and operations that are observable and those that are not. But we might also ask about which of the individuals in the domain of discourse $|\mathfrak{A}|$ of a model $\mathfrak{A}$ are observable. The preceding discussion implicitly assumes that each and every individual is observable, an unrealistic assumption for theories that trade in things too small to see. If there is indeed a workable observable/unobservable distinction, it applies foremost to events, situations, or states of affairs, while an individual or property or operation is derivatively one or the other insofar as it is a constituent of the event or situation. Moreover, a property, such as roundness, can be observable in some instances but not in others, depending on the individual involved. Thus, the putative distinction simply cannot be reflected in language as the positivists imagined. Also, a given individual may be observable in some types of circumstances but not others. The net result is that, to represent the empirical content of a theory, one needs to resort to fragments of its models that are not themselves fully fledged models, even for the observation language, but are only partial models in which, for some individuals and properties, it remains

indeterminate whether the individual has the property or not. We cannot get at the empirical content of a theory simply by bifurcating its language.

The Demise of the Syntactic View

Even before Carnap and the Vienna Circle, influential criticisms had been leveled against the received view. One was the charge that observation is theory laden. Another was the rise of scientific realism bolstered by the new causal theory of reference extended to natural kind terms.

These factors told against the bifurcation of the vocabularies of theories. Scientific realism, however, by and large continued to use the framework of theories as a deductively closed sets of sentences. Earlier on, even this had come under challenge largely because first-order logic was deemed too straitjacketing. Indeed, at best trivial examples of theories from mathematical physics had been axiomatized in first-order logic. This occasioned abandonment of linguistic features altogether in the development of the so-called semantic view, which holds that theories are rather classes of models, where the sense of *model* is broader than in logic.

THOUGHT EXPERIMENTS, SCIENTIFIC AND PHILOSOPHICAL

Thought experiments abound in philosophical literature and in many areas of scientific inquiry. Scholarly interest in thought experiments has increased over the past several decades. Whereas the role and status of thought experiments has been a point of focus for historians and philosophers of science for some time, philosophers have more recently devoted significant attention to this topic through books dedicated to it, themed special issues of journals on thought experiments, and many studies in journal articles and book chapters of this or that particular thought experiment.

Why has there been so much focus on thought experiments? There are many possible explanations for this increased attention, but three reasons are noteworthy. First, thought experiments, obvious from their name, seem to have something in common with real-world experiments. Determining the nature of that apparent similarity has drawn the attention of many scholars. Another reason is that thought experiments, especially those in the sciences, purport to inform us about the actual world, whether about what is actually the case or about what *could* or *could not* be the case. If thought experiments have this ability, many have wondered how merely *thinking* about some scenario can provide such insight. In other words, many thought experiments purport to provide knowledge of the world simply from one's armchair, but this appears to run counter to the thrust of much scientific inquiry. A third reason for the heightened interest in the status of thought experiments is related to the second: Thought experiments do not appear straightforwardly to sit well with contemporary versions of empiricism. As a result, many have worked to understand the epistemic import of thought experience on empiricist grounds. The entry first addresses

the nature and types of thought experiments. Next it discusses several prominent examples of scientific and philosophical thought experiments.

The Nature and Types of Thought Experiments

A thought experiment requires the reader to imagine some situation contrary to their past, current or even possible experiences. Thought experiments may appeal to times that the author admits never existed in the past, such as Thomas Hobbes's *natural state of humans*, or to scenarios even more abstract containing features like frictionless planes. In such imagined scenarios, the reader is often first instructed to examine carefully the features of the alternative setup. After this examination of the initial conditions, some change is usually introduced, such as the collision of one body with another body or the recognition that resources have become scarce.

Another common feature of thought experiments is that they are experiential in nature insofar as there is a transition through different stages of the experiment. Rather than merely imagining some static, counterfactual situation, a thought experiment provides the reader with a sort of mental experience. Thus, Charles Darwin asks readers to imagine wolves with differing levels of fitness competing with one another for prey as the number of prey shifts over time, Judith Jarvis Thomson illustrates the possibility of waking up and discovering a violinist who is connected to you and in need of life support, Thomas Hobbes imagines humans living without civil relationships and in constant fear of attacks from others as they face competition for resources, and in *Le Monde* René Descartes portrays a fictional world with its parts in the process of coming together. Just like experiences in the actual world and contrived experiments in a laboratory, thought experiments happen in stages like these and occur over a (fictional) period of time.

So far so good, but how could sitting in one's armchair and imagining scenarios like these—some very different from everyday experiences—promise to provide knowledge that will be usable in the actual world? Broadly speaking, there have

been two prominent approaches to understanding how merely the process of considering a thought experiment could do this: the *a priori* camp and the empiricist camp. After describing each of these prominent approaches, this entry will mention a third view that argues that thought experiments are empirical experiments in the mind. The *a priori* camp holds that some thought experiments transcend what it is possible to know from experience and as a result give those who work through them access to truths beyond experience, for example, the laws of nature. In a 2004 paper, James Robert Brown argues for this understanding of the nature of thought experiments by linking intuitions used in thought experiments to intuitions in mathematics. A consequence of the *a priori* account of thought experiments is that it implies that scientific inquiry is constituted by both experienced-based evidence, such as laboratory experiments, and *a priori* intuitions that transcend that experience. Against the *a priori* view, the empiricist camp tries to understand thought experiments as arguments that are not different in principle from an argument that one would make on the basis of experience or experience. For example, in a 2004 paper, John Norton argues against the *a priori* view by contending that thought experiments simply draw upon what is already known about the world. Sometimes a thought experiment may make explicit what was tacitly already known about the world, but a thought experiment adds nothing in addition to what experience teaches. On this empiricist understanding, thought experiments do nothing logically over and above what an empirically based argument would do; instead, thought experiments make those arguments more vivid than they would otherwise be if they were presented in argumentative form. An alternative view of thought experiments to these two suggests that thought experiments are empirical experiments. In a 1992 paper, David Gooding argues for such an approach by proposing that, rather than being empirical *arguments* that have simply been made more vivid, thought experiments are actual experiments conducted in mental laboratories. This approach highlights the experiential, narrative aspects of thought experiments draws attention to the fact

that many are often open to empirically based criticisms, just as laboratory experiments are.

Authors who use thought experiments in scientific and philosophical contexts do so with different goals in mind. It may be difficult or currently impossible to test some prediction of a theory, so a thought experiment may try to bridge that gap. Sometimes thought experiments seek to disprove the possibility of a claim. Other times they show the possibility of some claim given the initial conditions of the thought experiment. Still others seek to show the necessity of some feature given some broader theoretical component that is held. Despite these varied uses, and the many others that could be catalogued, some have tried to group thought experiments into broad kinds. For example, Sorensen's (1992) book offers one of the most comprehensive philosophical treatments of thought experiments and divides thought experiments into *necessity refuters* and *possibility refuters*. Alternatively, Brown's influential (2011/1991) treatment of thought experiments taxonomizes them into *constructive* and *destructive* thought experiments. These and the taxonomies that others have offered have been controversial, so another approach simply divides thought experiments into their many and various uses by particular authors. Rather than deciding this question of taxonomy, the remainder of this entry will examine several prominent examples of thought experiments, first in scientific contexts and next in philosophical ones.

Two Scientific Thought Experiments

Galileo Galilei and Falling Bodies

In *Discorsi*, a work from 1638, Galileo used the genre of dialogue to show with a thought experiment that Aristotle's claim that the speed of falling bodies differs according to their weight leads to a contradiction. The thought experiment arises when, during a discussion of Aristotle's arguments against the void, the character Simplicio notes an assumption that Aristotle makes related to the manner in which objects that differ in *heaviness* move in the same medium; the assumption is that such objects move at different rates of speed according to a *ratio as to their weights*. Simplicio takes this to imply, for example, that an object

that is 10 times as heavy as another will move ten times as fast.

After some debate between the characters Simplicio and Salviati about whether Aristotle ever actually tested this assumption by dropping objects with differing heaviness, Sagredo asserts that he himself *made the test* to see whether Aristotle's assumption would be upheld. Sagredo reports that the assumption did not hold up when he himself tested it. Salviati then interjects and denies the need for this or for any further empirical tests. Instead, he states that with a brief *demonstration* it is possible to prove that Aristotle's assumption is false.

The brief demonstration is a thought experiment. It begins with Salviati asking Simplicio if he agrees that the only way for the speed of a heavy falling body to increase or decrease is by the use of force or by some impediment. Simplicio agrees to this assumption, and Salviati further asks him whether he agrees that if two bodies with unequal speeds were connected to one another (to become a single, linked body) then in doing so the faster one would be slowed by the slower one and the slower one would be sped up by the faster one.

After Simplicio agrees to this consequence, Salviati asks him to imagine two stones, one a large stone that is moved by 8° of speed and the other a smaller stone moved by 4° of speed. Given the assumptions that Simplicio has agreed to already, it follows that if these two stones were joined together the speed of the compound stone would be less than 8° of speed. However, the new compound stone formed from the previously separated stones is *heavier* than the original stone that was moved at 8° of speed, and so we would expect it to move at a greater rate of speed than the individual larger stone. The contradiction should now be clear: the compound stone should both move *more* swiftly and *less* swiftly than the original stone, which moved at 8° of speed.

The beauty of this thought experiment is its simplicity as the reader follows through its stages from the initial assumptions to the exposure of the contradiction. The contradiction that the experiment exposes leads the reader to reject the Aristotelian assumption, and as Salviati states this seems to be something that can be done without conducting any empirical tests.

Charles Darwin's Origin and the Illustrations That Darwin Provides

Darwin's *On the Origin of Species* (1859) collected together observational data from many seemingly disparate sources. Darwin's own thinking on speciation was impacted by many sources, such as his own field observations and notes he took about them, the observations and actions of domestic animal breeders, and the many reports that he read on topics that interested him, such as those on the fossil record. The *Origin* begins with four chapters that seek to outline the theory of natural selection, beginning with consideration of the way that variation occurs among domesticated animals. Near the end of Chapter 4 (1859, 90 ff.), Darwin offers what he calls *illustrations* of how natural selection acts. Rather than obviously relying upon any particular person's empirical observations, these illustrations are thought experiments, which may come as a surprise to some of Darwin's readers.

In one such *illustration*, Darwin asks the reader to imagine a wolf that preys on different animals and also that that wolf's fastest prey has increased in numbers. Alternatively, he notes that one could imagine the same wolf and that its slower prey had decreased in numbers so that there would be a greater ratio of fast to slow prey in the resulting available pool. Given such an initial setup, Darwin suggests that the fastest and *slimmest* wolves would have the best chance of survival and would, as a result, be selected. Darwin furthermore contends those wolves that had the best chance of survival would likewise be more likely to leave offspring and that some of their young would inherit some of their traits and, after much time and many repeated instances, there could emerge a new variety of wolf.

What function does this and the other thought experiment *illustrations* that appear in Chapters 6 through 9 play within the overall structure of the *Origin*? In a 1991 paper, James Lennox argues that these thought experiments play the role of showing the reader the explanatory potential of the theory of natural selection to explain phenomena like the increase of a variety of wolf as well as its ability to handle potentially difficult phenomena. The thought experiment with the wolf thus seems designed to help the reader see—in the

sense of imagining the thought experiment play out in their mind—the ability of natural selection to account for the selection of one trait over another in such cases. Rather than simply making the *Origin* more rhetorically effective, these thought experiments seem to show how it is *possible* that the struggle for existence could result in variety through natural selection.

Two Philosophical Thought Experiments

Thomas Hobbes and the State of Nature

Thomas Hobbes described the *natural condition* of humans in chapter XIII of his well-known 1651 work titled the *Leviathan*. This is one of the best known features of his philosophy and is commonly called the *Hobbesian state of nature*. The imagined *natural condition* of humans is a thought experiment that Hobbes used to argue for an account of human nature that would serve as the foundation of his overall argument that the best arrangement for government is a commonwealth with a sovereign. In other works, Hobbes announced that his intention was to create a *science* of politics, which he claimed no one else had done before. This science of politics was supposed to offer certain conclusions like those found in the demonstrations of geometry, and the method Hobbes followed to do so required beginning with a thought experiment. In *De corpore* Chapter VII, Hobbes provided another thought experiment at the foundation of his first philosophy, geometry, and natural philosophy, which thought experiment is similar to the *natural condition* thought experiment. This entry, however, will examine only the thought experiment that he provides in his science of politics.

One of Hobbes's primary aims in *Leviathan* was to show that the only way to achieve lasting peace was to form a commonwealth governed by a sovereign with absolute, or nearly absolute, authority that would range over all aspects of public life, including religion. To show that this end would provide peace, in Chapter XIII of *Leviathan* Hobbes asked the reader to imagine a situation in which civil relationships do not exist at all and where there is a relative scarcity of resources. This imagined situation, Hobbes admitted, never existed and never has existed in such a

pure form, although he posited that there are some places where the conditions are close to it, and he also suggested that there is such a state internationally between sovereigns. Even with such limited actualization of this state, Hobbes intended this imagined scenario to teach the reader about human nature.

Considering humans in such a state exposes, Hobbes suggested, that there is a fundamental equality shared by all humans. This equality, however, is not what one might initially expect: It is a bare equality consisting only in the ability of any human to kill any other human, whether through strength or cunning. The next feature of humans in such a state is that owing to their equality they possess hope that they can achieve whatever it is that they desire, which desires are understood in terms of appetite and aversion. Next, Hobbes suggests that these desires would become frustrated when multiple parties desire the same thing. This leads to what Hobbes calls *diffidence* and a situation in which each person takes for themselves whatever is in their power to take. This is a horrible state to be in—as the reader undergoing the thought experiment can readily surmise—and those in it are filled with anxiety and grief because each person is always worried that an attack from another may come at any time. Such a state also lacks certain other features, which Hobbes holds shows us what is *natural* and what is artificial. For example, from considering this state, Hobbes argues that there is no justice or injustice present in this natural state using the following claims: In humans' natural state, there is no common power over all humans; without a common power, there is no law; and where there is no law, there is no injustice.

The thought experiment concludes at the end of *Leviathan* 13 by identifying three final features of all humans in the imagined state of nature. Each of these humans is moved by three passions: the fear of death, the desire for the things necessary for commodious living, and the hope that those necessary things can be acquired. Hobbes thus intended the thought experiment to demonstrate the dire situation of humans without civil relationships alongside each human's natural desire to leave that state because of these three passions. Hobbes meant the reader to agree with these claims because of their inherent plausibility,

made more vivid in the form of a thought experiment. The thought experiment thus shows the imaginer *what* their own life would be like without a sovereign, and the chapters following chapter XIII aim at showing *how* to escape that horrible state.

John Locke's Account of Personal Identity, and a Criticism From Thomas Reid

John Locke also offers a thought experiment related to the natural state of humans, but this section of the entry will focus on another of his thought experiments that has generated controversy. Indeed, Locke's account of personal identity was the subject of scholarly debate by his contemporaries, but it is also relevant to contemporary philosophical debates related to consciousness, memory, identity, and the notion of the self. To motivate his understanding of personal identity, Locke offers a brief thought experiment that considers the possibility of a human's *spirit* or *soul*,—which is, in some ways, in contemporary terms equivalent to their conscious mind—leaving its body and inhabiting another one. Such a thought experiment may have seemed like pure science fiction or mere religious speculation in the past, but recent advances in artificial intelligence may make the prospects of such consciousness transfer seem more plausible than it once did.

This thought experiment, which Locke offers in *An Essay Concerning Human Understanding* (II XXVII.15), begins by asking the reader to imagine that the soul of a prince “carrying with the consciousness of the Prince's past Life” enters the body of a shoe cobbler after that individual's spirit has left it. Were this to happen, Locke argues that the prince-in-cobbler's-body would be responsible for all and only the prince's past actions. Whatever good or ill that individual had done during his lifetime would be the responsibility of the prince alone. Locke asserts, though, that no one would consider this new prince-in-cobbler's-body to be the same *man* since “the Body too goes to the making of the Man.” Locke recognizes that, of course, to all others around him the prince-in-cobbler's-body would appear to be just the same cobbler as before. Nevertheless, the prince's soul in its new body would recall all the Prince's past actions and would be responsible for them.

For Locke, this thought experiment, wherein the reader imagines the transfer of a human's conscious soul from one body to another, was partly meant to show how it was possible for a *person* (Locke's term of art in this context) to be judged by God for their past actions even though they would not appear for such judgment in exactly the same body as the one in which they did those acts. In other words, Locke was concerned to make it intelligible that persons could be judged by God even though at their bodily resurrection they would not inhabit the exact same body in which they committed those acts. This link to judgment is why Locke later identifies *person* as a *forensic term* that applies to actions and their merit, and he states that it "belongs only to intelligent Agents capable of a Law, and Happiness and Misery" (II XXVII.26). Thus, according to Locke, and supported by this thought experiment, consciousness and memory are necessary for maintaining personal identity over time.

In Locke's own time, and to the present time, there were many criticisms offered of Locke's reliance upon consciousness and memory as criteria for understanding the nature of a person. What if one's memory fails? Does personal identity, and thus responsibility, also disappear? Locke himself recognized that there were potential difficulties for this reliance upon memory and considered, for example, how the law considers the drunk and the sober individual to be the same person (and issues punishments to sober person for actions that they committed while drunk), while such is not the case according to his own account. Locke responded to such worries by admitting that human laws are limited in some respects and noted that his interest in personal identity and responsibility related to the *great Day* of judgment wherein individuals would not be held responsible for what they did not remember (II.XXVII.22). Beyond Locke's own interests in understanding how judgment at the resurrection could be made intelligible, modern readers can think about whether memory and consciousness are the appropriate criteria for personal identity, and if so, whether they should be basis for attributions of moral praise and blame generally. Do blame or praise attach only to acts committed by the individuals who remember doing them?

A well-known objection by Thomas Reid criticizes Locke's account by offering its own thought experiment, designed to pinpoint difficulties with thinking about personal identity as necessarily linked with consciousness and memory. Reid asks the reader to consider a *brave officer* at three moments in his life: when he was punished as a schoolboy for stealing from an orchard (Moment 1), when he took the standard from an enemy during a battle (Moment 2), and when he was made a general later in life (Moment 3). According to Reid's objection, the reader is asked to imagine that at Moment 2, the individual remembers Moment 1, but that at Moment 3, the individual remembers Moment 2 but forgets Moment 1. As Reid puts it, such an individual at Moment 3 would have "absolutely lost consciousness of his flogging" (Moment 1). Using this thought experiment, Reid draws the following consequence: since Locke's understanding of personal identity requires consciousness and memory for identity to be maintained, the general both is and is not the same person who was punished at school for stealing from the orchard. The worry is that that Locke's account of personal identity results in a contradiction.

Further Reflection on the Nature of Thought Experiments

How would the two primary camps, already mentioned, understand these four prominent examples of thought experiments? Arguing on the side of the *a priori* camp, in Chapter 5 of his 2011/1991 book James Robert Brown calls the Galileo example a "Platonic Thought Experiment" because it both destroys the Aristotelian view and develops its own new account. Brown argues that it transcends experience because it does not involve any new empirical data being added, because the new theory is not deduced from existing data, and because the new theory involves more than a simple adjustment to the old theory. The empiricist camp, however, would criticize such an attempt, as Norton does in a 2004 chapter, insofar as it relies upon the notion that there are Platonic Laws. How could one justify the claim that it is possible to perceive such a realm of Laws and, even if one could, how could one know that that perception is accurate?

The placement of Darwin's thought experiments within the *Origin* seems to weigh in favor of the empiricist camp's understanding of them. Darwin's evidence is provided through varied observations from his own work as well as that of others, and the aim of his *illustrations* is to help readers imagine the range of ways selection could act, thus showing the explanatory potential of the theory. In other words, empirical data form the evidentiary core of the argument, and the illustrations build upon readers' existing tacit knowledge of the external world. Likewise, the Hobbes and Locke examples both seem to be more intelligible by thinking of them through the empiricist camp's understanding of thought experiments. If we view each figure through their own epistemology, which posits that there are no ideas apart from what comes through sense experience, whether external sense or internal reflection, both Hobbes and Locke would see the role of these thought experiments as making explicit what humans already know from experience. However, it is worth noting that such knowledge gained for each figure is in some sense *beyond* their everyday experiences. As mentioned already, Hobbes admits that there has never been any time like the natural state of humans, and Locke would not have seriously entertained the claim that any of his readers had witnessed or undergone the transfer of a soul from body to another. Nonetheless, both of these thought experiments draw upon experience even as they extrapolate from it.

TRUTH

Truth is a foundational concept. It has long been, and continues to be, indispensable to several domains of thought and practice, including government, law, science, and religion. Without the concept of truth, these practices would cease to be meaningful. Yet, the very idea of truth is difficult to capture. For millennia, philosophers have sought to pinpoint an essence or core property of truth, resulting in a wide range of complex theories. To this day, we lack an agreed-upon definition or theory of truth. Some philosophers have suggested that we simply discard the idea of truth altogether since there is purportedly nothing to define. Others have suggested that, rather than defining or rejecting the concept of truth, we should seek instead to understand what difference truth makes to everyday communicative practice. The result is that truth remains as controversial a topic in philosophy as ever. The entry traces the concept of truth from its roots in classical Greece through the coherence theories of 19th-century idealism, the work of American pragmatists C. S. Peirce and William James, the minimalist and deflationary views of more recent philosophers such as Alfred Tarski, and the links between knowledge, truth, and power as seen by continental philosopher Michel Foucault.

Correspondence Theory

The oldest and the most intuitive idea of truth is the correspondence theory, first proposed by Aristotle. In his *Metaphysics*, Aristotle asserts, “To say that that which is, is not, or that which is not is, is a falsehood; and to say that that which

is, is, and that which is not, is not, is true” (Aristotle, Γ 7.27) Aristotle’s assertion captures the idea that a true claim bears some sort of relationship with reality. While simple and commonsensical at first, a closer look reveals the difficulty of pinning down certain key concepts in this idea with precision. So, for example, what exactly is the nature of this correspondence? What corresponds with what? Is it a sentence, claim, or proposition that corresponds with reality? Is it an idea, image, or representation? It is a belief or state of mind? Consider also the nature of reality. When we refer to *reality*, are we referring to facts? If so, how are we to understand what counts as a fact? The very concept of facts is more problematic than it at first seems. Are facts impersonal items that we can collect, like rocks and leaves? Or do they have a social genesis? If the former, then we need to explain what facts are and how they can arise in the first place. If the latter, then truth would presumably correspond to something other than facts since our intuitive understanding of truth is that of something independent of human subjectivity. Thus, although many philosophers have historically endorsed the correspondence theory, they have nonetheless endorsed different versions of it: metaphysical and semantic. Despite this distinction, the correspondence theory is seen today as a decidedly metaphysical view; that is, a view that makes a strong ontological claim. While some philosophers still hold to the correspondence theory, they have nonetheless become a minority, as metaphysical claims are no longer as widely accepted in philosophy as they were in the past.

Coherence Theory

In response to the correspondence theory, the British idealists of the 19th century developed the coherence theory of truth. According to this theory, truth is a function of the internal coherence of a given belief system. A variation of this idea holds that a claim is true if it is consistent with other claims within the system. So long as that system allows us to make sense of the world around us, its degree of internal coherence can be understood as its measure of truth. The significance of this idea can be illustrated with an example from

science. If, for example, a scientific theory enables us to make sense of natural phenomena, and to conduct experiments and make predictions with meaningful results, then to the extent that the theory is internally coherent, then to that extent it is true. The coherence theory thus avoids the metaphysical problem of determining the nature of the relationship between claims or mental states and reality.

Although superficially appealing, the coherence theory nonetheless violates a common intuition about truth. If truth is a function of the coherence internal to a given belief system, then truth is relative to such systems. We can easily imagine rival belief systems with comparable degrees of internal coherence. Are they both equally true? What if they lead to different conclusions? Can incompatible conclusions resulting from competing theories both be true simply on account of the internal coherence of those theories? Truth would seem to be timeless and objective, not context-bound and relative. The coherence theory tells us more about belief systems than the phenomena they purport to explain. A second problem concerns the possibility of an incorrect belief cohering perfectly with other beliefs in a given system. If introducing an incorrect belief can still allow for coherence, then the coherence would seem to be a dubious criterion of truth.

Pragmatism: Classical and Contemporary

Recognizing the difficulty of the coherence theory, classical pragmatists such as Charles Sanders Peirce and William James took the view that truth can be measured in terms of its usefulness. On this view, the value of a given theory or belief system can be measured by how much it can deliver. This approach to truth enables us to differentiate between rival, internally coherent theories by determining which theory can produce more results. The theory that gives us more results is the truer theory. The gist of the early pragmatist view of truth is captured in James's assertion that "the true' is only the expedient in our way of thinking, just as 'the right' is only the expedient in our way of behaving." Although there is much debate about what James really meant by this vague

assertion, a common interpretation is that truth is simply *what works*. The practical appeal and non-metaphysical character of the classical pragmatist view notwithstanding, early analytic philosophers like Bertrand Russell strongly rejected this view on the grounds that it reduces truth to whatever is contingent and self-serving, and fails to specify criteria for *what works*. For example, astrology and homeopathy *work* for many people. Does that mean that either of them is true? This difficulty has led later pragmatists to rethink what Peirce and James were getting at and to offer a new interpretation and more plausible view of truth.

The neo-pragmatist philosopher Richard Rorty has been the strongest advocate in the English-speaking world for discarding the concept of truth altogether. Rorty follows Donald Davidson's view that truth is indefinable because it is a basic concept that cannot be broken down into more basic terms. Rorty further contends that truth is a metaphysical concept, like *God*, and that committing ourselves to truth is akin to submitting to God, that is, to something illusory. According to Rorty, getting rid of the concept of truth would make no difference to our social practices, like government and science. We could get by just fine without it. Huw Price has argued in turn, however, that we could not communicate meaningfully without the concept of truth, as truth implies the possibility of improving our existing claims and beliefs.

The philosopher Cheryl Misak has recently built upon certain passages from Peirce's writings to offer a new pragmatist view of truth. On her Peircean approach, truth should be understood in pragmatic terms, that is, the difference it makes to inquiry and linguistic practice. We would simply apply the term *true* to a claim or belief that appears to be indefeasible in practice, a claim or belief that we treat as capable of forever standing up to the test of practical experience. While this approach raises several questions, it nonetheless offers a non-metaphysical view of truth that answers Rorty's criticisms.

Minimalism and Deflationism

Recently, many philosophers have taken a minimalist and deflationary view of truth, regarding the truth predicate as having little meaning or

purpose other than to add emphasis to an already existing assertion or as shorthand for lengthier strings of assertions. On this approach, to say “It is true that the king of France is bald” is simply to add greater emphasis to the assertion “The King of France is bald.” Alternatively, to say “Everything in Book X is true” is taken to be a shorthand for endorsing everything asserted in Book X. Minimalism and deflationism do not treat the truth predicate as having no meaning or function, but rather see it as serving a limited linguistic purpose, one that still plays an important role in inquiry and communication.

The logician Alfred Tarski offered a kind of definition schema for the concept of truth that serves as the foundation for deflationist accounts of truth. According to Tarski, we can interpret the expression *is true* as a connection between an assertion and a state of affairs, and we can remain silent on the question “what is truth?” His account goes like this: All there is to an assertion that “grass is green” is true is that grass really is green *and* that if grass really is green then “grass is green is true.” This is expressed as:

“grass is green” is true if and only if grass is green.

According to this account there is no more to the truth concept than the collection of all possible instances of the schema.

Foucault, Truth, and Power

Whereas analytic philosophy has primarily focused on the meaning and pragmatic function of truth, the continental philosopher Michel Foucault has focused on the link between knowledge, truth, and power. Drawing from Friedrich Nietzsche, Foucault takes a much more expansive and historical view of truth. Rather than analyzing pragmatic function apolitically, Foucault proposes looking at all knowledge in terms of *truth regimes*: systems

of thought that vie with each other for institutional power, dominance, and influence. On this approach, truth is an effect of the competition for power: ideas and beliefs we treat as timeless and ahistorical, having lost sight of their historical genesis and character. Foucault’s genealogical view sees all truth and knowledge in terms of radical contingency. Given his historical and cultural approach to truth, Foucault’s genealogical method has been widely adopted in the humanities and social sciences to examine a wide range of systems of thought with the intention of understanding their power implications.

U

UNDERSTANDING

The way people think has long intrigued philosophers: *metaphysically* (regarding the nature of human intelligence) and *epistemologically* (regarding the nature of human reasoning) and, more recently, *psychologically* (regarding the scientific verification of naturally occurring phenomena in human thought). Theories of understanding try to explain the changes in the individual as well as describe the categorical differences across types of understanding.

Understanding moves us beyond the knowledge of isolated propositions to a more integrated grasp of the connections, relations, and significance of what we know. Indeed, we tend to think that knowledge, while important, is only the beginning of true understanding, which requires situating that knowledge within our entire cognitive economy. People often use terms of sensory perception in relation to developing understanding, such as “Now I see!”, but it refers to the satisfactory resolution of meaning concluded by the individual. An ancient admonishment highlights the difference between exposure and comprehension: “Hear now this, O foolish people, and without understanding; which have eyes, and see not; which have ears, and hear not” (Jeremiah 5:21). Understanding will integrate *experience discovered* (via personal perceptions) and *knowledge received* (from others’ reports of their own perceptions).

Graduated Understanding

Instead of a binary difference between understanding and misunderstanding, there is a common assumption that understanding can increase gradually. This may be explained by maturation of the individual, more complexity of one’s context, or a sequence within the nature of understanding. Although the arrival of the understanding may be experienced as an “aha” moment of inspiration, it is generally regarded as the cumulative result of many factors.

A lack of understanding can thus be attributed to insufficient opportunity to experience and process the concept in a meaningful context, with the additional factors of the individual’s capacity to do so and whether there is curiosity or interest. Because each of those factors will vary, the understanding is also variable in its pace and complexity. One’s degree of understanding may be described as incomplete, partial, or biased, but never permanently fixed the way one’s capacity might be determined. Understanding is expected to change, hopefully ever toward greater wisdom but nonetheless vulnerable to deception and ignorance of emerging new information.

Understanding is seen as a continuous process, with knowledge as the product of a degree of sophistication in its development. Knowledge tends to be accepted if it has been justified as true and is believable to society in general, but understanding is used as an indicator that the individual no longer experiences confusion. People are considered knowledgeable if they are competent in

the retrieval and application of information, but the people may not be regarded as having understanding if broader consequences and multiple perspectives are not apparent. Thus, many think of understanding not only as a continuous process but as part of a continuum of thought.

The active process of understanding is inherent in the taxonomy of the cognitive domain developed by the educational psychologist Benjamin Bloom (1913–1999) and colleagues, and in its revision half a century later. The taxonomy included three domains: *psychomotor* (movement), *affective* (feeling), and *cognitive* (thinking). The cognitive taxonomy was developed as a tool for assessment; that is, a way to measure the degree of cognitive proficiency as a result of different learning techniques. There have been many models of cognition, but Bloom's Taxonomy of Cognition (named for the lead researcher on the team) has become a standard way for educators to analyze learning objectives and to categorize student performance.

As shown in Table 1, two dimensions intersect: four types of knowledge and six types of thinking, or cognition. Understanding, the second cognitive process in the table, occurs in each knowledge dimension of *facts*, *concepts*, and *procedures*. The fourth dimension of knowledge is *metacognition* or self-awareness. Bloom's Taxonomy helps teachers be more accurate in their assessment of students' learning, and for that reason, the categories of the cognitive process dimension, such as *remember* and *understand*, are considered too vague for a learning objective. Instead, more specific verbs like those listed in Table 1 are used as indicators of mastering the level of cognition.

As used here, understanding is considered more advanced than simple factual recall, and it is also

considered necessary for the more sophisticated processes of analysis, decision-making, and creativity. The defining characteristic for this level is to be able to explain the meaning and context of the remembered information. The action verbs associated with the level in Table 1 suggest that understanding is in response to novel situations and in anticipation of future events. This taxonomy was proposed as a hierarchy from low to high levels of thinking, but there is not widespread agreement that the various types of thinking must occur in this sequence.

Understanding and cognition are not synonymous. Neuropsychological abilities include various aspects of thinking and reasoning, that is, understanding exhibited by *verbal memory*, *executive function*, *inhibitory control*, *processing speed*, *working memory*, and *vocabulary*. These cognitive functions are considered domain-general because they are used for all domains of experience. Researchers have devised reliable methods to test and measure these abilities, producing a large volume of literature informing our understanding of understanding.

Psychologist Howard Gardner's (1949–) theory of *multiple intelligences* expands this to identify many ways of knowing, challenging the traditional view of intelligence as defined by traditional academic proficiency. The separate modalities are not stable traits that limit individuals' capacities to understand, but rather a framework for many ways in which each individual can access information and process it meaningfully. According to Gardner, the frames of mind manage to span all aspects of human interaction with experience: the *cognitive* (logical–mathematical and verbal–linguistic), the *psychomotor* (visual–spatial, body–kinesthetic, and

Table 1. Verbs Representing Each Cognitive Process Dimension in Each Knowledge Dimension According to Anderson and Krathwohl's *A Taxonomy for Learning, Teaching, and Assessing: A Revision of Bloom's Taxonomy of Educational Objectives*

<i>The Knowledge Dimension</i>	<i>The Cognitive Process Dimension</i>					
	<i>Remember</i>	<i>Understand</i>	<i>Apply</i>	<i>Analyze</i>	<i>Evaluate</i>	<i>Create</i>
Factual	List	Summarize	Classify	Order	Rank	Combine
Conceptual	Describe	Interpret	Experiment	Explain	Assess	Plan
Procedural	Tabulate	Predict	Calculate	Differentiate	Conclude	Compose
Metacognitive	Custom	Execute	Construct	Achieve	Action	Actualize

rhythmic–harmonic), and the *affective* (interpersonal/social and intrapersonal/metacognitive).

Gardner insisted that our understanding of intelligence is ongoing. He and his colleagues introduced an eighth one focusing on understanding systems in context (naturalist) and at least one more proposed (existential). The pedagogical implication is that *multiple modalities* should be used to both develop and demonstrate understanding. The theory is supported by recent research confirming that specific neural activity is associated with each intelligence.

Developmental Stages of Understanding

Whereas Bloom's cognitive taxonomy categorizes different types of thinking, other theories of understanding focus on the person and how patterns of understanding will change across time. Eric Erikson (1902–1994) proposed eight psychosocial stages, each of which depends upon understanding, that is, the healthy resolution of predictable crises. Unlike the innate psychosexual stages of Sigmund Freud (1856–1939), Erikson's theory suggested that lack of understanding explains dysfunction occurring later in life, thus emphasizing the skills needed to navigate the landscape of inner conflict. This aligns with John Dewey's (1859–1952) hypothesis that understanding occurs only if there are problems to solve.

The capacity to understand clearly changes, prompting many theories to explain and predict it as a natural phenomenon. Jean Piaget (1896–1980), the Swiss developmental psychologist, focused on intellectual development, coining the term *genetic epistemology* for the changes he observed in children's capacities to understand different phenomena. He proposed that we respond to *cognitive dissonance* by either adjusting the new information to accommodate our schema for understanding the world or we adjust our schema in order to assimilate the new information. His theory suggested that interaction with objects was necessary for cognitive development.

The Soviet theorist Lev Vygotsky (1896–1934) outlined a sociocultural psychology featuring the *zone of proximal development* (ZPD). The ZPD is the expanded potential for learning found in being near someone with a larger knowledge base. The interaction itself was not the object of

understanding, but rather the context for improved understanding of interest to both people. This theoretical construct can help explain the well-documented success of *cooperative learning groups*, an instructional method requiring interaction between students sharing a task of solving a problem. American psychologist Carl Rogers (1902–1987) popularized the importance of a personal relationship to be established before a client could benefit from a therapist's guidance or a student could benefit from a teacher's influence. Understanding is therefore subject to a noncognitive context. Current pedagogical practice recognizes this as *social–emotional learning* that aligns with Bloom's affective domain.

Both Piaget and Vygotsky are considered *constructivists*, meaning that their theories emphasize the individual's understanding as personally distinctive from others' understanding. Constructivism as well as progressive pedagogy, emphasizing active engagement in real-world problems, have profoundly influenced schools to become more learner-centered and therefore more *developmentally appropriate*. Teachers are expected to be familiar with norms of cognitive development in order to maximize instruction for their students' understanding. For instance, children aged 5–7 begin to grasp cause-and-effect relationships plus more logical concepts of time and space, but their source of knowledge will still be concrete experience.

Canadian educational philosopher Kieran Egan (1942–) proposed an *imaginative* theory of learning that recognized five categories of understanding: *somatic* (physical functions and emotions), *mythic* (binary opposites), *romantic* (transcending one's own limits), *philosophic* (patterns and principles), and *ironic* (capacity for paradox and alternative thought). Each of these *understandings* is regarded, like Gardner's Multiple Intelligences, as different ways to arrive at truth and meaning.

Personal Understanding

As the preceding sections suggest, understanding is a personal event, akin to making sense of the world. Viktor Frankl (1905–1997), psychoanalyst and Holocaust survivor, identified humans' *search for meaning* as the primary function of life, explaining individuals who failed to thrive in the face of changed circumstances. Their personal meaning had

changed. Similarly, William G. Perry (1913–1998) did not assume individuals' stable character traits would predict ethical behavior. Instead, he focused on their progress through four stages of intellectual and ethical development, namely *dualism*, *multiplicity*, *relativism*, and *commitment*, as individuals progress through a gradually more complicated life. His scheme has been the basis for most subsequent ethical theories with multiple dimensions. A different view was presented by Mary Field Belenky (1933–2020) and colleagues, who challenged Perry's scheme first of all because it was based on studies limited to men. *Women's Ways of Knowing* added a novel first stage of *silence*, that is, being disconnected from knowledge. It reorganized the remaining stages of *received*, *subjective*, *procedural*, and *constructed* knowledge, the last of which would integrate all voices. Perry's scheme focused on the nature of knowing in response to changing contexts, while Belenky, in addition to women's perspectives and a broader group under study, focused on the sources of knowing.

VALUES IN SCIENCE

Values in science may refer to (1) the orienting aims or constitutive values of science as such or (2) the role of extrascientific values in the development of scientific activity. A related view that might be termed “values *and* science” concerns (3) the manner in which scientific knowledge and the esteem in which it is held in a given society itself shapes values.

The first view concerns the organizing principles as well as epistemic bases of science (i.e., what counts as scientific inquiry, evidence, or knowledge). The second view concerns both (a) the role played by extrascientific values in guiding the direction of science (e.g., focusing scientific resources on determining the nature of culture, on the causes of cancer, or on extraterrestrial matter) and in conferring authority on science, which has implications for science’s prominence and centrality in a given society, and (b) the role of values in conditioning scientists’ views of the world. The latter concern has been the subject of controversy in the philosophy of science as well as in the sociology of science, and it is at the heart of the debate between positivists, or naturalists, who see science as reflecting concrete and certain reality and being more or less impervious to influence by values, and social constructivists, or relativists, who claim that science serves to concretize values held by the culture in which it is developed.

Values and the Constitutive Values of Science

Values are the evaluative dimension of the basic constellations of shared symbolic orientation that structure action and human social experience. Values underlie rules, norms, and ethical practices, and they shape patterned activities. The attribute of shared orientation makes manifest the control that values exert on human behavior.

Science, like all other regularly patterned symbolically constituted activities, is a product of a peculiar set of values or shared symbolic orientations. Science may best be understood as a *patterned activity* characterized by a particular aim or goal: to attain objective knowledge of empirical phenomena. This aim constitutes science’s central organizing principle and thus shapes the activity of science as well as the standards according to which scientific knowledge is created. This aim, moreover, indicates the set of phenomena relevant for science as well as criteria for an appropriate method to be employed in pursuit of it. The various sciences (physics, chemistry, biology, sociology, etc.) are organized around sets of phenomena that are deemed relevant for the problems that motivate their scientific inquiry and that are indicative of their respective goals. In this way, each branch of science is special. The sets of phenomena that define them reflect the value placed on what is considered as worthy of being known. The constitutive values of science are intimately related to its aim and follow from it. The criterion of objective knowledge in science’s constitutive set

of aims demands that science be value-free or value-neutral in the sense of being resistant to extrascientific values such as those that are contained in ideologies or political imperatives.

The values of science denote those orientations that individual scientists and the scientific community should have if they are practicing good science. The reality of scientific practice, however, is indeed much more complicated. The sociology of science seeks to understand not only the value orientations of the patterned activity of science but also how practicing scientists interpret, transform, or stray from these values in practice. The line between good science and bad science is drawn by appealing to science's organizing principles, which are contained in its aim and the values that stem from it.

The core value or internal presupposition of science is the importance of solving a problem, which is to say that that which is yielded by inquiry is regarded as worth being known. The solution, moreover, must refer to empirical phenomena. Robert Merton, the esteemed American sociologist of science, argues that the term *science* refers to a number of interrelated albeit distinct concepts. One, it denotes a set of methods used to certify knowledge; two, it refers to the accumulated knowledge deriving from the application of such methods; three, it refers to a set of values and mores governing scientific activities; and, four, any combination of these. According to Merton, the set of values governing scientific activities makes manifest the following imperatives: universalism, communism, disinterestedness, and organized skepticism. *Universalism* denotes the value that the worth of scientific discovery is contained in the work itself and not in the personality of the work's creator. Criticism of science should not be ad hominem; positive appreciation of science should not be based on charismatic qualities of the scientist either. *Communism* denotes the value that work in science is communal: Great science is done, as it were, by standing on the shoulders of giants. Additionally, the value of communism demands that work be shared with the public. Privately held research betrays the values of scientific communality. *Disinterestedness* is a value that guides science toward something like sincerity in research. The aim of science is tied to the value of

the problem and solving it: This is its guiding light. Science is essentially not a means to fame, money, or power. *Organized skepticism* is the value orientation toward continual questioning and systematic testing of facts and theories. The avoidance of dogmatism stems from this value. These four features may be said to be four characteristic values of science. On this view, science manifests organizing principles that delineate it essentially from other kinds of patterned activities (such as figurative painting, imaginative literature, or religion). Honesty and objectivity are obvious values tied to those that Merton notes.

According to Karl Popper, the well-known 20th-century philosopher of science, the activity of science is characterized by the fact that its problems are formulated in such a way that demands that claims or theories be capable of refutation and that those claims are indexed to sets of empirical phenomena that are observable. A fit must be established between proposed solutions or theories and the relevant empirical facts as well as between descriptive claims about the relevant empirical facts and the objects described. It is clear that human judgment enters science during this process, not to mention at the initial stage where questions get formulated. The question is "How do scientists make judgments that are not informed by values?" The answer that has become the mainstream view over the past 50 years or so in the philosophy of science, in the sociology of science, and in science and technology studies is "they do not"—values are everywhere in science. On this view, scientists go out into the world looking for something, and out of the vast chaos of reality scientists impute an order and select questions considered to be important, evidence considered to be relevant, and tests and methods considered significant or appropriate. Popper is helpful here. He argues that an *expectation* or a *frame of reference* always precedes an *observation*. Values hence guide discovery. Popper refers to expectation-driven observation as the *searchlight theory* of science, which stands opposed to what he calls the *bucket theory*, which is something like a pure inductivist view of phenomena. No scientist can take everything into account.

With this in mind, it is clear that one of the basic value assumptions of science is that the

world is ordered. This shared symbolic orientation is a frame of reference in the Popperian sense. As the famous exchange between Albert Einstein and Niels Bohr over the development of quantum mechanics in physics made plain, one of Einstein's basic values was the belief in fundamental order: On several occasions, he expressed the sentiment that "God does not play dice with the universe." Einstein's frame of reference—his searchlight—is a value.

The Place of Extrascientific Values in Science

Values and the Direction of Science

In modern society, science is accorded positive social value. In this respect, science itself is a value. Science is not only revered but also constitutes the most authoritative form of knowledge of the current era. This was not always the case, however, nor is it a universal position: The honored position accorded science once belonged to theology and philosophy, and skepticism of science endures. The social value of science is an external condition of the activity of science itself—the social value of science neither follows from the internal logic connected with its aim or goal nor does it follow from the norms or characteristic practices of the activity itself. The positive social value accorded science is thus analytically separable from science. The positive social value of science is in this way an extrascientific factor.

Other extrascientific values bear on science, but, as has been argued by Robert Merton, Joseph Ben-David, and Liah Greenfeld, they do not affect the essential nature of the patterned activity or the criteria of evaluation internal to it. For one, there is the logical contradiction: If science were to be guided by a set of values that privileged the transcendental realm over the empirical/phenomenal realm, for instance, it would be clear that the patterned activity was not science at all but something approaching religion. As the pioneering sociologist Max Weber elucidated in his methodological writings on science and in his well-known *vocation* lectures, scientific values and political values are incommensurable. Each set of values might inform the other, but one cannot be reduced

to the other. Just as the game of soccer and gridiron football are guided by organizing principles that define them, so too are science and politics. If one introduces the rules of football into a game of soccer, one is no longer playing soccer. From a sociological standpoint, when the internal logic of a patterned activity is altered, it constitutes a new phenomenon. Weber, as much as anyone has done, recognized that values cross cut all human activities—science included. The key is to maintain a value orientation in science that actively seeks to keep extrascientific values out.

The direction of science is affected by recognized values in one significant respect—that concerning the problems considered worthy of being pursued. The value accorded solving problems related to various cancers, for instance, determines which scientific research programs receive funding, the degree of social approbation conferred on the research carried out, and which lines of inquiry are to be accorded priority. The urgency of the AIDS epidemic influenced the direction of research in biology, taking biology in a direction different from that of its previous course, and political developments (consider World War II and the Cold War) shaped the direction of research in physics.

The degree of development and prestige of science is under the control of values. As Merton argued in his classic text *Science, Technology, and Society in 17th Century England*, among the conditions for the explosive growth of science was the set of religious values of science's early proponents in England. Science was seen as a means of discovering God's intentions and the constitutive qualities of the natural order. More than this, the growth of scientific knowledge was envisioned as demonstrating the glory of God. Isaac Newton himself was a scientist who was motivated to pursue science in part by his religious values. Liah Greenfeld has complemented and amended Merton's thesis by demonstrating that the birth of nationalism in England helped bring about a shift in values regarding science, making the pursuit of science a national priority and an object of prestige. The pursuit of national prestige—a status value—constitutes in Greenfeld's thesis a significant part of the explanation concerning the sustained development of science. The pursuit of prestige is also a contributing

factor at the level of individual scientific achievement. The rush to publish one's results first, the expectation of receiving due credit for a discovery, and the hope of receiving a prize for one's work are all motive forces of science deriving from extrascientific values.

Values and Scientific Worldview

The role played by values in science has been and continues to be the subject of controversy. This controversy may be understood as a debate over two polar positions: one, that science is by definition value-free and only concerns the so-called facts of the world; and, two, that science is just a particular instantiation of human culture in general, and the view it offers on reality is no less conditioned and shaped by the complex of symbolic frameworks and shared symbolic orientations underlying values through which its activities and resultant claims are realized. These polar positions are positivism (or naturalism) and constructivism (or social constructivism/relativism). In its extreme version, positivism sees science as having privileged access to the facts of reality plain and simple, and general laws hence are drawn from facts. For its part, social constructivism sees science as one among many types of meaning-making or symbolic activities; in this way, the arbitrary standards typical of meaning-making processes are seen to impugn the credibility of the claims to value-freedom in science.

The view that conceives of science as dealing basically with observable and measurable facts and describing putative universal laws or empirical regularities without values or other extrascientific factors coming into play is termed *positivism*. Positivists adhere to a nomothetic ideal of science, which is to say an ideal that conceives of the world as under the control of general laws. Like all movements of thought, positivism encompasses a range of viewpoints. A uniting characteristic of positivist views is a strong belief that scientific facts are plain, unadorned, universally intelligible, and so forth. Based on facts thus understood, scientists draw out laws by generalization and extrapolation. Positivism not only rejects metaphysical explanation but also the view that social values play a determinative role in science. This view was the dominant scientific perspective

throughout much of the 19th and 20th centuries. Positivism was never the mainstream view in the sociology of science. It is no longer the mainstream viewpoint in the philosophy of science or other disciplines that study science and the production of scientific knowledge, although variants of this view continue to be held among the masses as well as among many practicing scientists and some philosophers.

The view that stands in contradistinction to positivism is *social constructivism*. A turning point in the commonplace positivist view of the relation between values and science came about with the publication of Thomas Kuhn's book *The Structure of Scientific Revolutions*. Although many philosophers and other scholars had advanced views that were destabilizing to the positivist foundation, Kuhn's book had a wide appeal that served, as it were, to tip the scale to the side of social constructivism. Kuhn argued that—contrary to the conventional wisdom that the logic of scientific development proceeded according to an internal momentum of the state of theory and that scientific knowledge was incremental, cumulative, and hence progressive—scientific theory was actually characterized by periods of systematic development (he called this normal science) that are interrupted by so-called revolutionary changes in its orienting paradigms. A *paradigm* is an exemplary finding or theory in which something like a strong consensus or shared positive appreciation obtains, and one might regard a paradigm as functioning axiomatically in times of normal science. Examples of paradigms offered by Kuhn include Aristotelian motion or the mathematical view of the electromagnetic field offered by James Maxwell. A major implication of Kuhn's view is that paradigms are accorded value and function as standards by which the adequacy of a theory or finding is judged. This view stands in stark opposition to the view of scientific development in which evidence is as if objectively measured against the theory according to methodological rules. On Kuhn's view, the structure of theoretical logic as represented by paradigms is regularly overturned and replaced by new theories that, since they follow different paradigms, are incommensurable.

The social constructivist view of science, which argues that values influence science implicitly

(e.g., in the construction of facts or in the determination of significant phenomena) and that broader social values shape the outcomes of scientific debate, interprets Kuhn as offering support to their view. Social constructivism suggests a view considerably stronger than the view that extrascientific considerations merely direct science in one direction or another: It argues that the facts and theories of science themselves are under the control of extrascientific values. The perspective of social constructivism is developed in the philosophy of science, sociology of science, science and technology studies, the sociology of scientific knowledge, as well as other disciplines and movements (e.g., feminist theory). A central contention of the social constructivist view is that values matter for scientific outcomes—change the values, and the outcomes change.

Values and Science

Scientific discoveries have played a role of their own in shaping the values of the wider culture. One important role in this regard concerns science's privileged status as a form of knowledge. Scientific explanation is regarded in modern societies as not only reliable but authoritative. Science has become the arbiter of so-called truth. As demonstrated by the public debates concerning the value of Charles Darwin's theory of evolution vis-à-vis the Christian biblical view on the origins of human life as well as the ontological questions these debates have given rise to, science is a force for shaping values outside its own sphere of knowledge production. Scientific claims have affected the values concerning standards of evidence in courts of law, the direction and course of medical care, and the allocation of funding to nations in need. What might be the most salient contemporary case demonstrating science's effect on social values concerns the claims regarding climate change made by the scientific community and the evaluation of values it has given rise to. The case of climate change also draws attention to the role played by scientific technology in shaping values by way of the ethical debates new technologies have prompted. The advent of the birth control pill, for instance, has played a role in shaping values regarding family planning, personality responsibility, and the advancement of women.

New medical technologies such as vaccination and organ transplants have led to evaluations of values so as to determine thresholds of acceptable risks. What complicates cases such as these is that determinations of acceptable risk often draw from science for evidence. Such examples illustrate that values crosscut human activities, yet the values characteristic of various activities remain distinct.

VITALISM

Vitalism is the doctrine that living organisms are essentially distinct from nonliving objects because they possess either a nonphysical property or a distinctive organization not found among nonliving objects. Historically, the vital property has been identified with a range of things, including a fluid, a spirit, or a life-giving substance. The ancient Greek physician Galen (129–216 C.E.) located the vital force in the air (*pneuma*) that is absorbed through the lungs and infused with blood in the heart. The French anatomist Xavier

Bichat (1771–1802) located the vital properties of living tissues in the form of *sensibility* and *contractility*, fundamentally irreducible properties (on par with gravity and elasticity in physics) that did not decompose. The chemist Justus Liebig (1803–1873) identified the vital force as a regulative function that controls absorption and waste release processes in plants and animals. The biologist Hans Driesch (1867–1941) identified a living force, or *entelechy*, in developmental processes. The philosopher Henri Bergson (1859–1941) argued that there must be a vital impulse or *élan vital* that is common to all forms of life and is responsible for the creation of all species.

Contemporary scientists are likely to dismiss the doctrine of vitalism for its mysterious nonmaterialistic ontological commitments. Philosopher David Hull (1935–2010) claimed that scientists and philosophers take ontological reductionism for granted, vitalism is dead, and that organisms are nothing more than atoms. Francis Crick (1916–2004), reflecting on his contribution to the helical structure of the DNA molecule to the investigation of life, is even more forceful, claiming that in light of molecular evidence, vitalists are *cranks*.

Yet, there are good reasons for taking vitalists and their motivating arguments seriously. Many vitalistic proposals (since the 19th century) were offered as a reaction to inadequacies or shortcomings of physicalistic explanations including its method of analysis, reductionism, interpretations of cause and effect, and adequacy conditions for empirical confirmation of unobservable or theoretical entities, especially for the kinds of complex systems associated with living organisms.

For instance, in reaction to Crick’s missive, the biologist C. H. Waddington (1905–1975) pointed out that physicists often postulate the existence of unobservables in order to account for peculiar observational effects or incomplete ordering schemes. A quark is considered a fundamental constituent of matter even if (at the time of postulation) it was not observed. Waddington’s point is that postulating unobservables is common practice in physics and hence should be acceptable in biology as well. In the philosophy of science, the question about how we should think about theoretical, unobservable entities is the basis of much discussion.

Another reason not to be overly dismissive of the vitalist doctrine is that not all vitalists appeal to nonmaterial substances as the basis for the distinction between living and nonliving organisms. Contemporary historians of biology have recently recognized another branch of vitalists—*enlightened vitalists*—in the 19th century who emphasized the type of articulation of the parts of organisms and their unique arrangements in the body as the locus for biology pertaining to understanding organisms. The French physician Ménéuret de Chambaud (1739–1815) suggested that the life in a body occurs as a connection of actions or an aggregate effect of interactions among various parts. He illustrated his point by comparing organismal arrangements with bee swarms, which strive together to hang on to a tree branch. Hanging on to a tree branch is not a characteristic of any individual bee, but it is what they do collectively. Likewise, life is not found in any part of a body, but it is a property that emerges from the arrangement contribution of all parts.

In sum, vitalism can be seen both as an attempt to explain the distinctness of living organisms and as a reaction to reductionistic explanations which refer to physical mechanisms and chemical structures. Vitalism emerged when some natural philosophers started to propose several distinct hypotheses that could be unified around the idea that life had inherent *vital properties* that differ from the sort of properties inorganic objects display.

Hans Driesch's Neovitalism

Hans Driesch was the most influential early 20th-century biologist to defend vitalism. In 1891, he performed experiments on sea urchins that appeared to contradict Wilhelm Roux's 1888 experiments on frog development. Driesch's initial interpretations of the experimental results were foundational for his vitalistic philosophical doctrine because Driesch did more than philosophize about the life-giving properties of organisms, he subjected his views to empirical testing.

Roux's experiment involved destroying half of the cells in frog embryos after the first stage of cellular division. Roux reported that the remaining cells continued to develop into half-embryos and conjectured that the function of each cell

played a unique part in the entire developmental process. Roux's work initiated the field of *Entwicklungsmechanik* or developmental mechanics. There is no need to postulate any vitalistic forces to explain embryonic development.

Driesch's sea urchin experiments, however, provided contradictory results: The nondestroyed embryonic cells continued to develop into full (but small) sea urchins. Driesch showed that it was possible to shuffle the blastomeres (cells produced by the first cleavage of the zygote, or fertilized egg) of early embryos with no effect upon later development. This suggested to Driesch that development does not involve a mechanistic predetermined process because any cell—regardless of where it is located in the system—had the potential to develop into a complete organism. Driesch did not deny that development involved chemical and physical processes, but he claimed that a complete explanation required the postulation of special conditions. Embryo development is not—as the practitioners of *Entwicklungsmechanik* believed—merely a matter of division of a germ that controls cellular division. Rather, development involves the response of a living organism and its immediate surrounding conditions.

On the basis of his experiments, Driesch proposed that behind living organisms there was a living force, called an *entelechy*, which would explain the seemingly anti-mechanistic behavior in developing embryos. The entelechy is present not just in embryos but in all organisms. It is a regulating agent that determines which of the various potential developmental outcomes the organism will realize. It also acts as a buffer against potential deleterious effects that organisms encounter from environmental conditions. Although the entelechy is nontemporal, nonspatial, it does not contradict any physical laws. For this reason, Driesch is often labeled as a *neovitalist*.

Vitalism and Organicism in the 20th Century

In the early 20th century, discussions about vitalism centered on two broad questions. The first is a question about metaphysics: What is the fundamental trait of living beings that allows us to draw the line between them and the inanimate world?

The second question concerns scientific methodology question in the investigation of life: If biology is a distinct science (other than physics or chemistry), what makes it distinct?

Among philosophers, Henri Bergson is among the most important vitalists around the end of the 19th century and the beginning of the 20th century. Bergson argued that there must be a vital impulse, an *élan vital* that is common to all forms of life and is responsible for the creation of all species. As a consequence, both mechanistic and traditional teleological approaches were, in his view, unable to account for changing and creativity, two characteristics necessary for evolution; Bergson advocated for a distinct form of finalism, compatible with the existence of the postulated vital impulse.

In 1914, the philosopher James Johnstone stated that organisms, when considered as a whole, provide disproof of the mechanistic explanatory paradigm. He argued that it is possible to study organisms from a purely physicochemical point of view and that reductionism to organisms to physicochemical phenomena is possible for methodological reasons (e.g., when scientists isolate parts of the organisms), but such approaches leave out something, since organisms should be considered as a whole. What is left out is a form of an *elemental agency* that would be responsible for the *direction and coordination of energies*.

For the Austrian biologist Karl Ludwig von Bertalanffy (1901–1972), an important lesson learned from developmental biology was its anti-reductionistic character. Although organic processes never run contrary to laws of physics and chemistry, life is more than a heap of physical and chemical processes. It is a particular arrangement and organization of physical and chemical processes.

By maintaining a commitment to physical processes while at the same time emphasizing a special characteristic of organic life, Johnstone and Bertalanffy were harkening back to the Enlightenment vitalism of the 19th century. Subsequent proponents of this approach are called *organicists*. Organicists reject the vitalistic doctrine that postulates the existence of nonmaterial life forces. Yet, they retain the idea that there are systematic features of organisms that distinguish them from

nonliving entities. Three defining themes of the doctrine of organicism are:

- *The centrality of the organism as the starting point of biological theorizing.* Just as the concept of energy occupies a central role in physics, the concept of an organism is the unit from which biological concepts and laws derive.
- *The importance of organization, as opposed to matter, as the defining characteristic of living organisms.* Organicists tend to eschew references to entelechies and substances in favor of emphasizing large-scale collective effects.
- *The autonomy of biology with respect to the physical sciences.* Organisms are more than complex machines in virtue of their distinctive kinds of organization. For example, growth is more than predetermined genetic programming; it involves intricate timing and ordering. Biological understanding of organic life requires concepts and laws that are particular to biology and have no counterpart in physics.

Vitalism and Evolution

Vitalism in relation to evolutionary theory is motivated by considering the role of organisms and their immediate surroundings in an explanation for adaptive design. After the early 20th century discovery of Gregor Mendel's (1822–1884) work on genetics, evolutionists tended to view the relation between development and evolution as unimportant for the investigation of the processes of natural selection. Yet, 21st-century research on the role of interactions between developing systems and the various surrounding signals and forces in the production of adaptive structures have revitalized interest on the contribution that organisms make to the processes of evolution. Organisms are not merely passive objects at the nexus of internal (genetic) and external forces. Organisms do not merely respond to physical conditions of their environment; rather, they play an active role. As biologist and philosopher Richard Lewontin (1929–2021) argued, organisms and environments are co-determined or co-constructed. Organisms contribute to evolution in a variety of ways. They actively select features of their surroundings which are relevant to their own survival, and in doing so, they change

their surroundings in ways that affect other organisms. This new emphasis on organisms provides a new way of investigating inheritance, development, and evolution and has, among other things, launched the field of evolutionary, ecological development or *evo-eco-devo*.

Philosopher of biology Denis Walsh has extended Lewontin's view by arguing that organisms are goal-directed agents. Hence, the proper scientific investigation of organisms and their role in the processes of natural selection requires understanding the way that organisms initiate and receive changes in forces and signals. This is best accomplished by adopting a methodological vitalism and embracing a suit of concepts and theories that are often shunned by biologists including *goals*, *affordances*, *salience*, and *teleology*. Many of the features of Walsh's vitalism are encapsulated in the tenets of organicism, as described above.

The Gaia Hypothesis

The Gaia hypothesis is the hypothesis developed by the independent scientist James Lovelock (1919–2022), according to which the Earth should not be considered just the environment where life appeared and developed but should be taken as a fully integrated with the dynamics of the biosphere, such that life, in a relative sense, would be fully and systematically integrated with the planet as a whole. The Gaia hypothesis appeared explicitly when Lovelock and the biologist Lynn Margulis presented evidence for the idea that, since life appeared on Earth, the atmosphere has always been in homeostasis with life, even in periods of change. Far from being the result of mere chance, they argued, this is explained by the hypothesis that, when life appeared on the planet, it took control of the environmental conditions that would favor the further development of life. They concluded that the Earth's atmosphere should be considered as a component of the biosphere, instead of just the environment that provided conditions for the development of life.

In the following decades, Lovelock explored the Gaia hypothesis in detail, stating that the Earth should be considered to be alive, and providing evidence for and against this idea. This

hypothesis suffered criticisms and modifications over the years but is discussed even nowadays as a plausible account in ecology, atmospheric sciences, and evolutionary biology. As Lovelock himself and others have argued, self-regulation of Earth doesn't imply some sort of teleology (though initial formulations of the hypothesis had left this open to interpretations) and is compatible with natural selection as we understand it nowadays. Still, the Gaia hypothesis includes the thesis that life cannot be isolated and described just by stating the biochemical conditions within organisms; instead, life should be seen as fully integrated and harmonized with external forces, dynamics, and conditions. In this sense, as observers have pointed out, the Gaia hypothesis resembles the form of criticism that vitalists addressed to some mechanistic accounts of life, as addressed in the previous section of this entry.

W

WARRANT

The concept of *warrant* is a contemporary notion adopted by some philosophers—among whom Alvin Plantinga stands out—that derives from the classical concept of *justification*. Both warrant and justification are concepts used in epistemology to describe and evaluate why a subject *s* holds a belief *p*. In that sense, warrant and justification are intertwined notions that sometimes are used interchangeably and sometimes are used as two different notions; this makes it difficult to establish a clear dividing line between the two concepts. Perhaps the less controversial difference between warrant and justification has to do with the differences between the externalist and internalist accounts in analytical epistemology: that is, the difference in what types of entities or phenomena can justify a belief. The notion of justification is typically internalist because it reserves the justification of a belief to what is in the subject's perspective of the world (i.e., internal states of the subject, such as other beliefs, serve to determine when a belief *p* is justified). In contrast, the concept of warrant is typically externalist because it holds that the justification of a belief is determined by its relation to the external state of affairs (i.e., external sources can be used to justify a belief *p*).

Within a general framework of controversies about the meanings of both warrant and justification, Plantinga raised a general criticism of the

very idea of justification that, according to his vision, is shared by the different expressions of internalism (and by some philosophers akin to coherentism, reliabilism, and even externalism) that dominate British and American epistemology. Contemporary epistemologists, such as the *classical* Roderick Chisholm and Richard Feldman as well as William Alston, Laurence Bonjour, Alvin Goldman, and John Pollock, present a great deal of confusion concerning what the connection is between justification and rationality, justification and knowledge, and justification and evidence. The main argument is that these different accounts of justification constitute varieties of the thesis according to which knowledge (i.e., what it is to know that *p*) can be analyzed conceptually as justified true belief (i.e., *s* is justified in believing that *p* is true). In contrast, Plantinga proposed that justified true belief is neither necessary nor nearly sufficient for knowledge. Hence, warrant is whatever precisely makes the difference between knowledge and justified true belief.

Warrant, the Gettier Problem, and the Proper Function Condition

The notion of warrant is connected to the question of the epistemic value of a justified true belief. In this vein, some philosophers—such as Michael Bergmann and Tyler Burge—present the notion of warrant as a project of responding to the philosophical challenges that the Gettier problem has implied regarding the definition of the idea of

knowledge. In 1963, Edmund Gettier famously demonstrated that a belief may be justified and true but still fail to be knowledge (i.e., a justified true belief is necessary but not a sufficient condition for knowledge), which called into question the ancient Greek philosopher Plato's idea of the definition of knowledge. Since then, Gettier's three-page article has stimulated a renewed effort in philosophy to clarify what knowledge constitutes.

Hence, the difference between a justified true belief and knowledge is that a belief can turn out to be justified and true by *epistemic luck*—that is, by error—and therefore not be knowledge. Consider one of the two cases that Gettier raised in his seminal article, which has been followed extensively by similar cases and analyzed by other philosophers, such as Roderick M. Chisholm, Alvin Goldman, and Brian Skyrms. Suppose that Smith and Jones have applied for a certain job, and suppose that Smith has strong evidence for the following conjunctive proposition *p*: Jones is the man who will get the job, and Jones has 10 coins in his pocket. Therefore, Smith concludes (justifiably, by the transitivity rule of the identity) the following proposition *q*: the man who will get the job has 10 coins in his pocket. In the end, Jones does not get the job; Smith gets the job. In addition, upon opening his pocket, Smith discovers he has 10 coins in it. Consequently, his belief *q*, according to which “the man who gets the job has 10 coins in his pocket,” was justified and true. However, Smith's belief turns out to be true by epistemic luck and therefore is not knowledge.

The Gettier cases demonstrate that a belief can be justified and true (in the sense of corresponding to the facts) even though the epistemic operation that supports it, in most cases where it would be used similarly, would lead to error. However, the formal process does not catch this error. These types of cases have two points in common. First, justification is fallible. In other words, the belief is justified and true, but this is not a sufficient condition for knowledge. Second, chance intervenes in the formal process of justification. These two points are combined in such a way that epistemic luck *compensates* for the weakness of justification and erroneously transforms into knowledge a justified true belief that was not in reality knowledge.

Plantinga suggested that the prevention of this potential error depends on the correct use of all subject's intellectual faculties (what he called the *proper function condition*). Only the correct use of all subject's intellectual faculties can be the *warrant* that the result of subject's epistemic procedures generates knowledge and not merely true belief. Thus, defined as a proper function condition, warrant is that which allows one to distinguish between knowledge and justified true belief. In other words, Plantinga presented the idea of warrant as a condition to solve the famous Gettier problem. Any theory that fails to consider the proper function condition as necessary for warrant is subject to Gettier-style counterexamples.

Warrant, Justification, Internalism, and Externalism

The notions that justification and warrant share both evoke the idea of the epistemic value of a particular belief—that is, if, when, and how one can give a certain type of support to a particular belief (i.e., to have a sufficient warrant or justification to hold a particular belief). However, the concepts' definitions depend on the different epistemological approaches in which they are used. In this sense, following the differences between internalism and externalism, what in general terms separates the notion of justification from that of warrant refers to what types of factors can act to provide epistemic support to a belief. Internalists use the term *justification* more to maintain that a belief's epistemic value is determined by a subject's internal states or reasons, whereas externalists use the term *warrant* more to maintain that a belief's epistemic value includes facts external to a subject's reasons.

The thesis of internalism can be formulated as follows: The internal states of the subject bearing the belief are what determine whether the belief is justified. It is common for internalists to resort to two premises to support this idea: (a) a belief is justified only if one has good reasons for accepting it, and (b) only the subject's internal states (e.g., other beliefs or other mental states) can be considered reasons to believe (or to accept a belief). In contrast, externalism maintains that the facts determining a belief's epistemic value embrace external conditions, such as whether the belief is

caused by external sources that make the belief true. In this vein, externalism emphasizes states of affairs that are external to the subject. In other words, externalists tie warrant to properties external to mental activity.

Burge proposed a currently highly influential variety of the externalist notion of warrant as *perceptual entitlement*. Perceptual entitlement constitutes a type of epistemic warrant that, unlike justification, can account for the intuitive fact that certain creatures are often warranted to hold perceptual beliefs, even when they lack reasons for them or do not have the concepts needed to reason regarding them. Such creatures may be entitled to believe because they possess highly reliable perceptual systems that, although incapable of producing reason, produce nonconceptual representational states providing warrant for their perceptual beliefs. According to Burge, epistemically unsophisticated creatures such as prelinguistic children and higher nonhuman animals represent paradigmatic examples in this regard.

Warrant, Justification, Foundationalism, and Coherentism

If the distinction between internalist and externalist conceptions of epistemic values is relative to the *nature* of the epistemic justification (what types of entities or phenomena can justify a belief: internal justification vs. external warrant), then there is another classification of theories about epistemic values that involves the *structure* of justification. Depending on how the structure of justification is conceived, one can distinguish between foundationalism and coherentism, among other approaches.

Generally associated with the idea of warrant, *foundationalism* leads to the argument according to which if a belief is justified, then it is either a basic or noninferentially justified belief (it receives no justification from another belief) or an inferentially justified belief (it receives justification from another belief). In contrast, *coherentism*, generally associated with the idea of justification, leads to the argument that there are no basic or noninferentially justified beliefs, so if justified, then inferences from other beliefs would justify every belief.

Thus, foundationalism defends the existence of two types of beliefs according to their justification: that is, basic or noninferentially justified

beliefs and derived or inferentially justified beliefs. In this vein, certain interpretations of the idea of warrant—such as Burge’s notion of perceptual entitlement—play the role of non-inferentially justified beliefs (i.e., beliefs not requiring justification). In contrast, coherentism maintains a *doxastic monism*: that is, the thesis according to which all beliefs are of the same type regarding their justification, and all beliefs are inferential (i.e., all beliefs receive their justification from other beliefs).

Hence, foundationalism maintains an architectural conception of the theory of epistemic values. Justification is seen as an asymmetric and linear structure. The set of beliefs is conceived as a *building* whose foundations are noninferentially justified beliefs on which the other beliefs (i.e., derived beliefs or inferentially justified beliefs) are based. Basic beliefs do not require the same sort of justification and function as the *warrant* of inferentially justified beliefs. Basic beliefs do not receive their justification from any other belief, either because they are self-justifying (given their nature) or because they receive their justification from other kinds of entities or phenomena (i.e., nonbeliefs), such as perceptual experience.

Unlike foundationalism, which characterizes the theory of justification as an *edifice* in which certain beliefs are not required to be justified and in which such beliefs function as a warrant for inferentially justified beliefs, *coherentism* characterizes the theory of justification as a *network*. According to this conception of justification, one’s system of beliefs is a *lattice* structure: that is, a network of multiple and mutual relationships among beliefs in such a way that this connection and not any specific beliefs in a unidirectional way (i.e., the foundational or non-inferentially justified beliefs in foundationalism) serves as a justification for any of the system’s beliefs. A belief is justified if it is part of a coherent set of beliefs and to the extent that its inclusion increases the coherence of that set of beliefs.

Coherentists’ main criticism of foundationalism posits that there are no satisfactory asymmetric and linear justifying chains, and an arbitrary interruption of the chain of reason occurs. In contrast, foundationalists argue there are beliefs that no longer need justification, and this is the role that the idea of warrant occupies in

foundationalism. Foundationalists' main criticism of coherentism affirms that coherentism is unsuccessful because it sees warrant as involving only the relation among beliefs and does not consider that the nexus between external environment and belief is also crucial to warrant.

WORLDVIEW

Worldview may be defined as a pretheoretical framework of belief that offers individuals and societies an account both of what the world is and what the world should be. The term functions as a calque, or borrowed translation, from the German term *Weltanschauung*. Thus, *Welt*, or world, and, *Anschauung*, or perception, results in an anglicized rendering as *world-and-life vision* or, more briefly, *worldview*. Established usage in the United States is *worldview*; the *Oxford English Dictionary* hyphenates the term as *world-view*, although some scholars in Commonwealth countries follow the widespread practice of omitting hyphens in compound words. Hence, both

worldview and *world-view* are legitimate renderings of *Weltanschauung*.

The Salience of Worldview

Academic inquiry in late modernity has witnessed an exponential increase in the sheer number of theories, many claiming to explain the same phenomena, often in radically conflicting ways. To take but one example, the field of communication studies, which arose amid public speaking instruction and media effects studies in the mid-20th century, has spawned numerous theories of communication, explaining the phenomenon in terms of symbolic construction, interpersonal interaction, information systems, semiotic shifts, media effects, social influence, ideological change, and many other dynamics too numerous to list here. Few of these theorists are able to agree even on the definition of the phenomenon they supposedly share in common: One disciplinary expert, Stephen Littlejohn, notes some 126 different definitions of communication. Other disciplines experience similarly centripetal spreading of theoretical developments.

Coping with this profuse changefulness has tempted scholars to seek an all-encompassing account—or what philosophers would call a univocal account—for why 10 theorists can address the same phenomenon with 10 distinct but apparently viable theories. Given the elusiveness of such an account, however, other scholars have instead attempted to explain cross-disciplinary and intra-disciplinary differences by appealing to a given theorist's intuitive conceptual framework or worldview. Because this concept mediates between deeply held beliefs and empirical experience, it can enable productive exchange among scholars whose ideas might otherwise get lost in intertheoretical translation.

The Structure of Worldview

Expositors of the worldview concept generally begin by turning to the first major theorist of worldview, Wilhelm Dilthey (1833–1911), a German philosopher and psychologist. He grounds his account of worldview in what he calls life itself. Although life is lived out in innumerable various ways and is notoriously resistant to analysis, it

nonetheless exhibits some commonalities across the human species. One such commonality is that the person cannot help experiencing the surrounding world as something more than a set of causal, material forces. This inescapable sense provokes reflection, especially about the vanity of life, the changeableness of the world, the intense pleasure of everyday life, and the inexorability of death. Dilthey insists that everyone experiences these dynamics of life differently, but all must reflect on them as the largest questions of existence. Such reflection gels, as it were, into particular ways of knowing the world.

These ways of knowing are prior to empirical inquiry or theoretical investigation. To be sure, careful theoretical reflection can abstract the basic beliefs that constitute a particular way of seeing the world. But the sources for worldview beliefs are not wholly determinate. For example, a person experiences the people that populate her everyday life as a relatively stable matrix of relationships. A sociologist could theorize about each of this person's relations in empirical terms: who enjoys more or less social influence, who is likely to succeed or struggle economically, what needs or expectations determine their well-being. But no such analysis can univocally account for the lived experience of these relationships, because such experiences are themselves constituent aspects of life as lived by people down the ages. No theorist can evade these experiences or the perspective they engender, because they function presuppositionally before empirical method and theoretical inquiry get down to work.

Dilthey makes clear that a worldview's basic presuppositions constantly confront larger realities than theory-makers usually attend to. In all the bewilderments of life, questions about where the person originates, how she matures, and where she is destined are constantly at the center of the human's deepest reflection. In response to especially terrifying realities of life and death, individuals and societies have always developed shared worldviews that console, explain, or animate human endeavor, whether they have found themselves in an ancient Egyptian temple or a Baptist pulpit or a college library.

If worldviews are pretheoretical, can anything be theorized about their formation or structure? Dilthey would say yes. Worldviews are formed, he

explains, as we struggle to discern how to comport ourselves in response to experience. These attitudes toward the world, which Dilthey classifies in terms of optimism or pessimism, make up the basic materials of religion and literature, mythology, and philosophy. If we study how these frameworks of belief take shape, we can spot certain stable patterns of development. First, the person, as a perceiving subject, will develop a vision of reality, or what Dilthey calls a cosmic picture. Within this picture, she watches the events, the objects, and the people of her own life. Her perceptions gradually help her establish meaningful connections between all these things. These connections then form a platform for the second stratum of a worldview, the basic emotional evaluations of lived experience. Does she find something disgusting? Does she find a person delightful? Does she find an experience boring? In each case, these judgments will create a platform for the third layer of her worldview: her behavior in the world. Guided by her cognitive vision of reality, animated by her emotional responses to experience, she will seek a rightness and wholeness in the middle of her relationships. Gradually, layer upon psychological layer, from cognitive vision to impassioned evaluation to volitional determination, the person will build an ever more encompassing view of the world framed by beliefs that she holds to be universally reliable. A mature worldview will enable her to seek to bring her life into line with the Good as she understands it. For Dilthey, then, worldview becomes a regenerative concept—*generative* in the sense of giving shape to life, *regenerative* in the sense of allowing for innovative shaping of life.

Dilthey's account of worldview focuses on the interiority of the world-viewer. This preoccupation with the inner life of the world-viewer made sense within Dilthey's milieu of German Idealism and Romanticism that prevailed from the late 1700s to the mid-1800s. But it may also have given short shrift to more materialist dimensions of worldview formation. Friedrich Nietzsche's (1844–1900) materialist critique reworked the concept of *Weltanschauung* in a way quite opposed to Dilthey's commitment to truth: In short, Nietzsche treated worldview as nothing more than a consequence of power moves and structures. One contemporary theorist of worldview who

takes seriously both Nietzsche's critique and Dilthey's account of worldview is the contemporary Canadian philosopher James Olthuis. In his essay "On Worldviews," he lays out a Diltheyan exposition of the structure of *Weltanschauung* but does so with a phenomenology that takes into account the problems of materiality and ideology raised by Nietzschean critique.

Whereas Dilthey might be said to use the worldview concept to explain differences that arise between and among philosophical theories, Olthuis instead focuses on differences that arise between worldviews themselves. He traces the evolution of these differences from the idealism of worldview's first expositors to the materialist and historicist expositions of theorists like Nietzsche, Karl Marx, and Sigmund Freud and on to conceptual developments made by linguists, philosophers of science, sociobiologists, and religionists. For each of these groups, Olthuis notes a tendency to elevate one element—politics, economics, sexuality, language, faith, and genetics—as the determining formative factor for *Weltanschauung*. In contrast with such reductiveness, Olthuis's phenomenological theorizing proposes that worldview emerges among all these factors as they shape and are shaped by each other.

The problem for worldview, as the concept has developed through late modernity, is how to reconcile its aspirations for universality and its tendencies toward perspectivalism. Olthuis proposes to deal with this problem by treating the concept as a mediating entity between a person's deepest beliefs about the world and her diverse experiences of that world. The mediation that worldview performs is bidirectional: belief shapes experience, just as experience shapes belief. This allows Olthuis's account of worldview to take seriously both people's sense that their worldviews are dealing responsibly with the biggest questions of existence and critical theorists' sense that people are often unaware of how determined their beliefs are by cultural or biological forces. On the one hand, people deal with big questions by committing themselves to large answers. On the other, people must acknowledge the indispensable influence of traditions, societies, educational systems, not to mention physiological and psychological conditions. In other words, they cannot get behind these things to some pure, interior identity whose

beliefs are unaffected by cultural forces. But their worldview, says Olthuis, can mediate between these two dimensions of human life—belief and experience—toward the creation of a more integral personality.

This mediation between the beliefs to which we entrust ourselves and the cultural conditions in which we live makes for an account of worldviewing that is at once flexible and risky. Accordingly, Olthuis addresses what happens when worldviews fall apart. Sometimes people's anxieties create a divide between belief and experience, as when someone professes to believe in an ethic of compassion and yet practices an ethic of severity. Other times, people disguise efforts to maintain economic or political or institutional security by rationalizing their own power moves as ethically responsible. Consequently, worldview formation depends a great deal on both psychological well-being and social awareness. Olthuis acknowledges at times a worldview crisis can become so severe that people are forced to alter their deepest beliefs, though often in ways that they can recognize as maturation.

The History of Worldview

These accounts of the structure of worldview risk fixing a concept that has shown a remarkable flexibility in its short history. In contrast with the term *theory*, which traces back to an ancient Greek word (*theorein*) for the highest seat in a Greek theater, the worldview concept emerged only as late as the 1790s, when Immanuel Kant (1724–1804) apparently coined the term. In *Critique of Pure Judgment*, Kant's neologism *Weltanschauung* referred to the capacity of the human mind to intuitively apprehend the world. The new term became immensely popular in German intellectual culture by the 1830s, before spreading with memetic quickness across Europe.

Several factors seem likely to have contributed to the rapid popularity of the worldview concept in high modernity. For one thing, the term depends on an immensely influential ocular metaphor for describing epistemology. Of course, a commitment to visualist ways of knowing is hardly a modern invention. Indeed, the early Greek word for *theory* evokes a philosophical habit of looking steadily at something, thus detaching the theorist from the

changeable flow of everyday life and granting a platform for contemplating universal truths. This universalist emphasis, as Hjordis Becker notes, appears in Kant's development of the worldview term as a universalist concept for the knowing seer of the world, as well as in Dilthey's exposition of worldview in large, abstract typologies for religion, art, and philosophy. But although the term *worldview* continued the long-established habit of uniting knowing and seeing, Walter Ong has noted the ways that the rise of early modern science and the maturation of print technology altered and intensified the visualist tendencies of Western culture. Although Kant could coin the term *Weltanschauung*, and Dilthey could theorize it, neither could predict the semiotic shifting of the worldview concept, especially its shifting toward the perspective of the individual seer.

The newly invented term could hardly have enjoyed a more fortuitous historical moment for achieving currency. But the conditions that made it quickly popular also sped its evolution in conspicuously individualist and aesthetic directions. Charles Taylor has traced how these individualist dynamics found further support in notions of the interior self, cultivated by the introspective and egalitarian priesthood of all believers in the Protestant Reformation and extended by the Western tradition's conflicted support for two ideals at once: extraordinary heroism and ordinary life. These individualist forces, so supportive of the personalist vectors in the worldview concept, would achieve an eventual critical mass in the German Romantic movement of the 18th and 19th centuries, when thinkers like J. G. Fichte, F. W. J. Schelling, and Friedrich Schleiermacher repositioned the knower not as a theorist contemplating the inert glory of being but rather as a world-viewer making sense of the historical contingencies constitutive of everyday experience. As Albert Wolters notes, this repositioning represented a shift in attention from *ousia* (what is permanent and essential and universal) to *Geschichtlichkeit* (what is changeable and historically particular). This romanticization of epistemology enabled the worldview concept to develop not only in rational but also in aesthetic directions—directions still discernible today in many theorists' predilection for talking about worldview in terms of narrative and imagination.

The aestheticism of the worldview concept has from its origins created a tense relationship with the rationalist aspirations of theoretical inquiry. But perhaps no thinker put the work of world-viewing in tension with theory-making more vigorously than the Danish philosopher Søren Kierkegaard (1813–1855). In works such as *Either/Or* and *Fear and Trembling*, he depicted different ways of understanding life in terms of the aesthetic, ethical, and religious worldviews, or to use the term he preferred, *life views*. His literary criticism made clear that for him, one hugely important criterion for evaluating artistic effort was whether or not the artist helps people develop their own mature life views.

The worldview concept also caught the attention of religious thinkers, especially in those branches of Christianity emergent from the Protestant Reformation. Perhaps the most well known of religious worldview theorists was the Dutch prime minister and theologian Abraham Kuyper (1837–1920). He articulated the Reformed Christian faith in terms of a life system antithetical to other systems such as paganism, Islam, Roman Catholicism, and modernism. Kuyper's Scottish contemporary James Orr (1844–1913) also drew upon the concept of worldview, as an expression of the human yearning for a holistic account of the universe, in order to combat modernism. In the 20th century, philosophers like Herman Dooyeweerd (1894–1977) and Francis Schaeffer (1912–1984) helped to ensure that evangelical descendants of the Reformation would give more attention to the worldview concept than any other group of philosophers or theologians—an impressive distinction given the pervasive popularity of the worldview concept. As worldview historian David Naugle notes, *Weltanschauung* enjoyed a remarkable and virtually unparalleled flourishing in countries far from its first blooming and development.

The Uses of Worldview

Any exposition of the worldview concept in late modernity must address the fact that many intellectuals have appropriated the worldview concept under terms of their own devising. As an initial example, Karl Marx's (1818–1883) and Friedrich Engels's (1820–1895) notion of ideology showed

significant overlap with *Weltanschauung*, although Marxist philosophy distinguishes between the two by saying that ideology is more focused on socio-economic concerns than is worldview. This widespread reappropriation under other names raises the question of why the worldview concept has struck many people as useful, while the term itself has not. It may be that the scholars using the term have tended to do so in an institutional environment that privileges novelty and innovation: The publishing requirements of the academic guild have a built-in momentum toward neologism. Perhaps, too, the very popularity of the worldview term has resulted in a sloppiness that invites theorists to rename it for the sake of definitional precision. Furthermore, if, as some theorists claim, all theorists of worldview have a worldview themselves, they can hardly help redesigning terms that more closely align with their own worldviews. In what follows, this entry traces three different major appropriations of the worldview concept: phenomenological, scientific, and linguistic.

Phenomenological Appropriations

Keenly concerned about the seeming exhaustion of rationalism and idealism, Edmund Husserl (1859–1938) developed a new branch of philosophy called phenomenology. He argued that although disciplines like geometry and the physical sciences appear to be autonomous, they are actually planted in a pretheoretical world that nourishes those disciplines' significance. Once uprooted from this pretheoretical ground, even the most rigorous of disciplines wilts and collapses. In response to this exhaustion, Husserl developed a reflective mode of recovering the human experience of originary life in hopes of replanting theoretical inquiry in lived experience, where it could flourish. Thus described, Husserl's phenomenology sounds a great deal like a Diltheyan critique of naturalism. But Husserl was vigorously critical of the worldview concept for being contaminated by historicist and relativist tendencies.

At first, Husserl attempted to correct worldview by advancing what he called *Weltanschauung* philosophy. This philosophical enrichment of worldview arrives when careful critical reflection pursues wisdom and thus achieves a richer, fuller

development of what would otherwise be possible for the subjectivist perspective of the world-viewer. Husserl also tried to locate an even more rigorous mode of thought called *scientific philosophy*, which Naugle summarizes as the means for eliminating disagreement and worldview-ish relativism, as well as the establisher of foundations for scientific disciplines. But Husserl eventually despaired of this project, not least because Europe seemed to be overrun by personalist, subjectivist philosophies, which he attributed to the popularity of worldview. The danger, as he saw it, was not simply a loss of meaning through relativism; the danger was a loss of potential agency and action through cultural exhaustion. Husserl came to recommend that all human thought and practice be grounded in a recovery of an intuitive experience of the *Lebenswelt*, or lifeworld. This lifeworld arrives for the knowing subject, before she can superimpose theoretical categories upon it. The reflective person can regain both significance and strength by attending *Lebenswelt* as an enfolding dimension of experience prior to theoretical inquiry and rational conceptualization.

Are there commonalities between Husserl's lifeworld and the concept of worldview? Both concepts are pretheoretical. Both are attentive to the lived experience of the individual. Both have universal aspirations, though Husserl believed his notion of *Lebenswelt* could avoid charges of relativism better than worldview. Perhaps the most profound difference between the two concepts emerges in Husserl's profound distrust of history. In contrast with the more historically grounded notion of worldview, a lifeworld, at least in Husserl's telling, transcended all change and contingency, giving access to an enfolding, universal, even eternal, matrix for all human inquiry. The concept eventually came to exhibit more flexibility in the phenomenological tradition than Husserl granted it. Maurice Merleau-Ponty (1908–1961), for example, developed a historically informed *Lebenswelt* grounded in the human body. The importance of *Lebenswelt* as a kin concept to *Weltanschauung* for Husserl and Merleau-Ponty should not obscure the work of other phenomenologists, such as Karl Jaspers (1883–1969) and Martin Heidegger (1889–1976), who have addressed, at great length, the psychology and problems of worldview.

Scientific Appropriations

Despite the fact that worldview theorists have often treated scientific inquiry as a kind of foil for *Weltanschauung*, two scientists have achieved notoriety by drawing on the worldview concept in order to think through the philosophy and history of science: Michael Polanyi (1891–1976) and Thomas Kuhn (1922–1996). Polanyi's *Personal Knowledge*, published in 1958, appropriates worldview-ish thinking in his theory of tacit knowing. Arguing that we can know more than we can say, Polanyi insisted that what we know explicitly and theoretically is only a part of what we know tacitly and existentially. Consequently, we can only come to know reality by committing ourselves to living within a fallible worldview, or what Polanyi called an *interpretive framework*. What keeps such a framework from being solipsistic or relativistic? He wards off both concerns by counseling that the knower should toggle among three foci of attention: language, theory, and experience. Put differently, we shift our attention from the language we use to the theories we construct to the experience we live. In order to explain how this toggling enables indwelling an interpretive framework, Polanyi uses the simple but evocative example of a medical student who is trying to make a diagnosis using an X-ray film: At first, the student can see nothing on the X-ray but the patient's ribs; but as she listens to veteran radiologists talk about the X-ray, gradually she can come to see past the ribs to the pulmonary symptoms beneath. In other words, listening to the radiologist's *language* about their *experience* of the X-ray shapes their *theory* about the pulmonary condition. But what enables the student to make similar diagnoses is a tacit commitment to an indispensable interpretive framework. The radiology example might suggest that Polanyi's tacit frameworks bear only on limited, tightly framed problems. But he understands tacit knowledge to range from the smallest elements of empirical experience to the farthest reaches of intellectual and even religious inquiry. Polanyi would say that tacit commitments are indispensable for anyone trying to make sense of how language, theory, and experience bear on a vision of reality.

A much better known cousin to Polanyi's notion of interpretive framework emerged in

Thomas Kuhn's account of scientific discovery and problem-solving in his 1962 book *The Structure of Scientific Revolutions*. Part history of science, part philosophy of science, *Structure* argues for a sociology of scientific knowledge in which empirical inquiry pursues answers to communally agreed-upon problems within the ambit of what Kuhn calls a *paradigm*. The shared methods, instruments, beliefs, and problems that make up a given paradigm create the conditions of what Kuhn calls *normal science*. Within normal science, researchers agree on certain problems, make use of a common language (such as empirical formulae), and practice a shared comportment or attitude toward the problems before them. Sometimes, their paradigm proves unable to solve these problems or explain away various anomalies, which, if they become sufficiently numerous and persistent, create a crisis and bring about a scientific revolution. Researchers who embrace the resultant *abnormal science* will endure an untranslatability, or incommensurability, between the ways they used to see a given problem and the way their new paradigm requires them to see that same problem.

Kuhn used the term *paradigm* so diversely throughout *Structure* that even a sympathetic reader counted some 22 different meanings for the term. The terminological diffuseness of *paradigm*, however, may have made it especially suggestive for other fields and disciplines, many of which embraced the term in widely divergent ways. In a 1969 postscript to *Structure*, Kuhn himself tried to discipline his own semantics by delimiting two meanings for the term. His first sense of *paradigm* indicates what a community believes, values, and does in the practice of scientific inquiry (p. 175). This sense notices the community that forms among like-minded scientists and asks how we can explain what members of that community share in common that enables them to speak comprehensibly and to come to agreement when studying controversial phenomena. Kuhn's answer is they share a paradigm. Some scientists would prefer Kuhn to use the word *theory* instead of *paradigm*. To which he responds that that word, at least in its current usage, is too limited in scope for the holistic framework Kuhn is describing. (He later tried to switch out *paradigm* for *disciplinary matrix*. The new term never caught on.)

Kuhn's second sense of *paradigm* indicates the profile of a particular kind of problem, which, if grasped, enables scientists to solve other, apparently unrelated problems in analogous ways. This sense of the term counters conventional notions of scientific theory that assume that solving a particular problem requires only that one knows how to apply a pertinent theory with its concomitant rules. But Kuhn argues instead that the most important knowledge the scientists need for problem-solving exceeds both theory and rules. Scientists need to know not only the correct procedures for how to solve a problem but also a kind of transferable knowledge between problems. This knowledge bears less on cognition than on *praxis*: The scientist needs to spot analogies between apparently dissimilar problems and then to engage these new problems with the same approach required by already mastered problems.

How comparable are Polanyi's and Kuhn's accounts of tacit frameworks and paradigms to the usage historically attributed to worldview? Both thinkers highlight the sociality of knowledge and its incommensurability for people outside a given scientific community. Both emphasize the importance of the tacit and the praxis-based for the practice of scientific inquiry. But although worldview and Polanyi's notion of an inarticulable interpretive framework address large metaphysical questions, Kuhn's notion of a paradigm does not. A group of scientists could work within a paradigmatic understanding of physics or chemistry without addressing questions about the origins or destination of being. Such questions are not, of course, unrelated to wave motion or covalent bonding, but scientists taking up with the problems deemed appropriate to a given paradigm are not necessarily equipped by that same paradigm to address larger metaphysical questions. A paradigm, of course, can exhibit worldview implications. Indeed, some readers of Kuhn worried that his paradigmatic account of science was metaphysically relativistic. He responded to this criticism by saying that paradigms are always based on empirical evidence—which brings up a second difference between worldviews and paradigms: The latter are evidentially based. Worldviews may of course be grounded in empirical evidence, but they may as often as not be formed by other sorts of inquiry

as well, such as spiritual practice, hermeneutical inquiry, or ethical reflection.

Linguistic Appropriations

Thanks to the so-called linguistic turn in philosophy, in which theorists such as Ludwig Wittgenstein and Donald Davidson theorized language as a constructor, not simply a reflector, of reality, many theorists in the 20th century have remarked upon the reciprocal relationship between language and worldview. These theorists might be placed along a spectrum from those who hold that language gives shape to worldview to those who hold that worldview collapses into language. Among those who see language as constructive of but distinguishable from worldview, the linguist and rhetorician Kenneth Burke (1897–1993) developed a concept called *terministic screens*, very much in keeping with *Weltanschauung*. Burke noticed that despite scientific accounts of language as largely descriptive, people's use of symbols actually did much more than describe. Language, he noted, does at times *reflect* the world, but it also *selects* parts of the world for the language user to attend to and *deflects* other parts of the world away from the language user's awareness. For example, a pharmaceutical website may inform a website reader about aspects of a drug's ingredients, clinical effects, and any interactions with other drugs, but not discuss the sociological implications of the drug's usage or the rhetorical aspects of its marketing. This omission need not be underhanded: directing attention to one thing and not to another is an essential aspect of symbolic action. Accordingly, when we select a terminology, we are choosing a way of seeing the world. Burke appropriated the Augustinian maxim that we believe in order to understand by saying that we entrust ourselves to a way of speaking in order to see what it enables us to see.

Burke believed that the world existed independently from terministic screens. Later appropriators of a linguistic account of *Weltanschauung* were not so sure. Their doubts encouraged the notion that worldview is a kind of epiphenomenon of linguistic exchange. Richard Rorty has argued that humans invariably make use of a terminology to argue on behalf of what they do and believe, to account for what their own lives might

mean, and to praise or condemn what they hold to be good and evil. Rorty refers to this way of speaking as a *final vocabulary* because the terminology is *final* in that it cannot be argued for apart from the resources of language. A holder of the vocabulary might use a given terminology to defend almost anything, except itself. Questioning a person's final vocabulary moves that person to one of two recourses: the use of force or an attempt at redescribing the terminology in some new or appealing way. Rorty contrasts two basic approaches to these final vocabularies: common sense and ironist. The commonsense vocabulary invites an un-self-conscious articulation of ultimate beliefs as if they were ultimate truths that any rational being should assent to. Ironists, in contrast, know talking in *this* way and not *that* way enables people to see things as either good or bad, with the result that no ironist can allow herself to be complacent about her current habits of talk.

Are the linguistic frames described above equivalent to worldviews? Linguistic appropriations of *Weltanschauung* have the strange double consequence of both emphasizing and decentering the subjectivity so integral to the worldview concept. Rorty's final vocabulary, more than Burke's concept of the terministic screen, emphasizes the importance of individual subjectivity and the private projects of the self. On the other hand, they also diffuse the notion of a private, interiorized, centered, essential self. Burke's account of terministic screens, while not denying the inner life of the language user, is less concerned with what a language user internally means by such and such a term than with how language is functioning in and around the speaker. Rorty's notion of final vocabulary does even more to decenter the subject, to the degree that the self is nothing more than a tissue of sentences. Terministic appropriation of *Weltanschauung* both powerfully privileges and strangely diffuses the self.

The Critiques of Worldview

Despite the relative youthfulness of the worldview concept, it has enjoyed a remarkable popularity among both academics and the lay public. But perhaps in part because of the many and diffuse ways the term has been appropriated, it has also

endured stiff critique. This section traces three basic appraisals of *Weltanschauung*, focused on what worldview suggests about theory, subjectivity, and discourse. These criticisms tend to focus less on the worldview concept as defined in this entry than on reductions that tend to emerge when theorists use it sloppily.

Questions About Theory

The worldview concept is all too easily reducible to a rational system of beliefs and ideas, especially in apologetic or educational contexts, where movement from an intuitive, pretheoretical understanding to a determinate, theoretical explication feels necessary. But such a reduction loses track of what Charles Taylor has identified as the lived experience that is always the foundation for one's understanding of the world. In his analysis of contemporary religious belief and unbelief, what seems to make late modernity so decidedly secular is not that so many people have embraced one monolithically secular worldview (the sort of univocally irreligious or scientific system that Kuyper or Husserl feared). Instead, people today find themselves living with *conditions of belief* that make many different kinds of secularism and religiosity apparently reasonable and respectable. Worldview constructed theoretically could easily miss the conditions that make belief or disbelief possible, even when successfully naming the ideas that constitute a given framework of belief.

Questions About the Subject

The idealistic and Romantic roots of *Weltanschauung* make it vulnerable to critiques of individualism. Worldview can of course be understood communally. But as the philosopher William Rowe has argued, worldview only makes sense if we first posit a prior subject. At times, this subjectivity is construed in rationalist terms, especially when worldview is understood in a more systematic and cognitive fashion. At other times, a worldview-ish subjectivity tracks with a more aesthetic, Romantic notion of the self. But in any case, *Weltanschauung* seems to necessitate a peculiarly modern anthropology founded in a centered, interiorized conception of the self. Students of premodern accounts of the self, as well as theorists

of postmodern anthropology, will recognize the limitations of this latent individualism within the worldview concept.

Questions About Discourse

Olthuis's account of worldview as a mediating concept (see under "The Structure of a Worldview") helps explain why the interaction of language (itself a medium) and *Weltanschauung* is so complex. Does language provide a matrix from which worldview emerges? (As Rorty would seem to say.) Or is worldview prior to language? (As some of Rorty's realist opponents would seem to say.) This complexity makes it easy for theorists to resort to reductionisms. Rhetorician Celeste Condit has traced academic assumptions that discourse and ideology are entirely exchangeable for each other. Again, as with the overly theorized or subjectivist accounts of worldview, such reductionism emerges most frequently when theorists attempt to use the worldview concept as analytic equipment. When a politician delivers a speech, critics can show how the discourse functions in tandem with the speaker's worldview. In such cases, the speech is sometimes assumed to express a worldview without remainder. But there are other cases, as Condit points out, when material and emotional dimensions in speech function in excess of the speaker's worldview. For example, a politician may, through powerful pathetic appeal, move an audience to an action that might otherwise contradict their belief system.

Even with these critical questions in mind, the worldview concept has distinguished itself as an elegantly useful one for theorists capable of addressing the need for both stability and universalism in a modern and late-modern world highly sensitive to contingency and subjectivity. The fact that it also demonstrates a conspicuous elasticity under a broad range of theoretical sobriquets suggests that some variation on the concept will be assisting theoretical and pretheoretical inquiry for a long time to come.

Appendix: Resource Guide

Because the topic covered in the encyclopedia is not a standard academic discipline with its own journals and foundational textbooks, we have here elected to include an eclectic mix of resources for students encountering issues related to theory in STEM and wishing to explore them further. First are seminal books in the history, philosophy, and foundations of theory. This is followed by a list of journals broken into three parts more or less mirroring the organization of the encyclopedia: philosophy; formal disciplines in STEM; empirical disciplines in STEM. Finally is a list of websites for a range of STEM discipline organizations.
